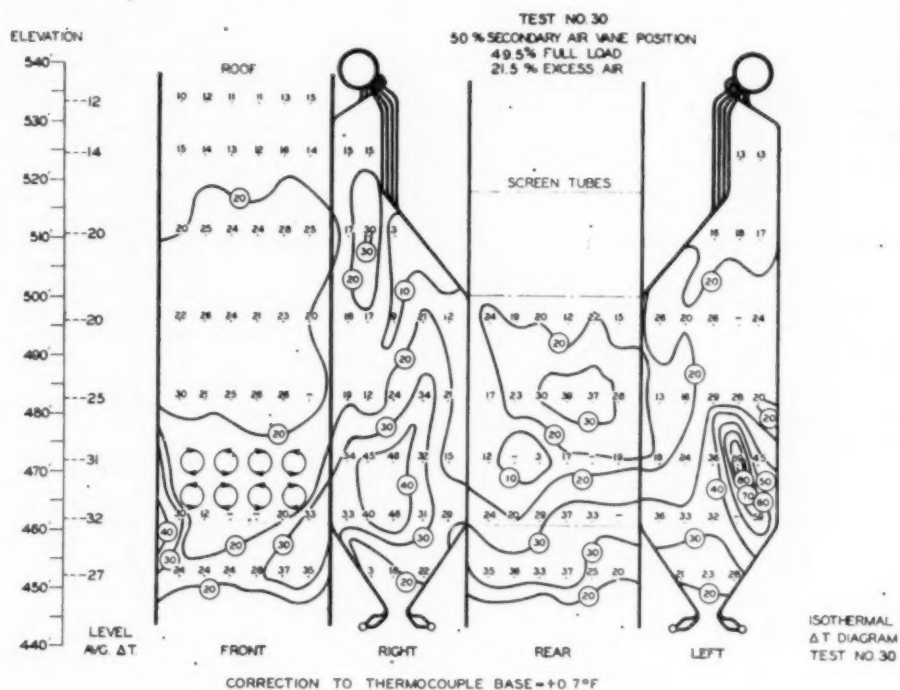

FIG. 19 Isothermal ΔT and Ash-Coverage Diagram Test No. 30

U_o = over-all conductance of metal and film = 1060 Btu/(sq ft) (hr) (deg F)

S = total projected area of furnace surface = 8884 sq ft

ΔT = average difference in temperature between surface at furnace-face center line and temperature of mixture within tube as indicated by base thermocouples

$$\begin{aligned} U_o S \Delta T &= 1060 \times 8884 \times \Delta T \\ &= 9,417,000 \times \Delta T, \text{ Btu per hr} \\ &= 9.417 \times \Delta T \text{ MKB per hr} \end{aligned}$$

Furnace heat-absorption efficiency then becomes

$$\text{Efficiency} = \frac{9.417 \times \Delta T}{\text{Net heat available to furnace}} \times 100$$

The value of heat absorption for the ΔT method has been determined for each complete test as well as furnace heat-absorption efficiency. Fig. 21 shows a comparison of the furnace heat absorption as obtained from the ΔT -results with the furnace heat absorption as determined by heat-balancing the furnace. This curve shows that, in general, a fairly good correlation is obtained between the two methods.

ANALYSIS OF RESULTS

Table 3 shows the average of all board data and all other pertinent operating data, such as burner-box pressures, burner settings, pulverized-coal fineness, etc., taken during the tests.

Table 4 shows the distribution of pulverized coal between burners on each test in per cent of total coal flow to the furnace.

Table 5 shows the average value of ΔT obtained at each furnace-face thermocouple location.

Table 6 presents a summary of the important test conditions and results for all complete tests.

Figs. 5 to 19, inclusive, show the distribution of heat absorption in the furnace and furnace-wall cleanliness for all of the operating conditions studied.

Figs. 22 to 28, inclusive, show the distribution of heat absorption over the height of the furnace for all of the operating conditions, and these curves are arranged in groups to facilitate the study of the effect of the various operating variables.

Figs. 29 to 32, inclusive, show the furnace heat-absorption efficiency, as determined by the ΔT -results for all of the operating conditions studied.

Owing to the inherent errors involved in any calculations, based upon the ΔT -values, the analysis of these data necessarily must be qualitative. The curves have been drawn to indicate trends in the distribution of heat absorption and furnace efficiency for this particular furnace under the operating conditions studied.

Referring to the ash-coverage diagrams, it is found that, in general, the furnace walls remain relatively clean under all of the operating conditions investigated. The only furnace-wall surface which accumulated any appreciable amount of ash is that surface of the rear wall located directly opposite the burners. In this location the ash coverage varies with operating conditions and the surface periodically cleans itself. The ash coverage on the side walls is negligible and is confined to small fingers which project out from between the tubes toward the direction of gas flow. The front-wall surface has no ash coverage other than a light dust coating about $1/16$ in. thick. Heavy formations of ash somewhat similar to stalactites were found hanging vertically down from the bottom of the slag-screen opening on all tests. These formations varied in size for the different tests since their accumulated weight occasionally would cause them to break away and fall to the ash pit. The average diameter of these formations at their base was 8 to 10 in. and their length approximately 12 to 18 in. They were held in place by their base, form-

ing at the location where the rear-wall tubes were bent out of line to form the slag screen. Similar ash formations were found at the bottom of the rear-wall sloped section. Here the ash appeared to be dry and sintered and again built up until the accumulated weight caused it to break away. These pieces were of the same general size as described previously and could be broken off easily. It is possible that a small eddy was located in this corner of the furnace and aided the growth of these formations.

Referring to the isothermal ΔT -diagrams, it may be seen that zones of relatively high absorption rates existed in that area of the side walls adjacent to the burners under all operating conditions. These zones, in general, indicated absorption rates in the vicinity of 50,000 to 75,000 Btu/(sq ft-hr), whereas the average absorption rate for the entire furnace is approximately 40,000 to 45,000 Btu/(sq ft-hr) at full load. The absorption rates found in these zones for some operating conditions are probably higher than those experienced in the normal operation of this furnace, since normally the secondary-air vanes are adjusted as required to obtain the optimum furnace conditions with no flame impingement. On these tests we used the vane adjustments to provide changes in flame shape so that we might study its effect upon furnace performance.

The sloping section of the rear wall which forms part of the ash hopper also showed relatively high heat-absorption rates in all cases, apparently due to the cleanliness of the surface in this area and the fact that this surface has an excellent "view" of the flames. The heat absorbed by the rear wall, where the surface is not affected by ash coverage, is generally higher than found on the other walls. The highest average absorption rates for any elevation are found in the lower part of the furnace and usually reach their maximum at the elevation just below the burners. The maximum might occur at the burner elevation if the furnace-wall surface in this area were not affected by ash accumulations.

A wide variation in absorption rate is found at the burner elevation for the various operating conditions studied, again indicating that this area is affected by ash accumulation which varies with operating conditions, or cleans itself periodically. On the curves representing the distribution of heat-absorption rates over the height of the furnace, it is found that the heat-absorption rates decrease in going to the higher furnace elevations, but that a second peak of increased absorption rates occurs in that part of the furnace where the cross-sectional area is reduced by the sloping section of the rear wall. Since this same characteristic is noted for all operating conditions, it seems that, at least partially, it is caused by an increase in convection transfer in this region due to the "scrubbing" action of the furnace gases against the wall surface as the cross-sectional area of the furnace is reduced. This is also shown by the isothermal ΔT -diagrams where zones of slightly higher absorption rates are found at this elevation on the side walls and the front wall.

The furnace heat-absorption efficiency was indicated to be approximately 41 per cent at full load, under normal operating conditions.

The effects of the various operating variables on distribution of heat absorption in the furnace and furnace efficiency are analyzed under separate headings which follow:

Effects of Varying Secondary-Air Vane Opening. Based upon our experience with these burners, we investigated this variable in the range of 40 to 60 per cent vane opening at full load and 35 to 65 per cent vane opening at 75 per cent full load. These ranges of vane opening provide sufficient variations in flame shape and still maintain satisfactory furnace conditions.

(a) 100 per cent full load—25 per cent excess air (test Nos. 15 to 17, inclusive): Under these conditions, it was found that the amount of ash accumulated on the rear wall opposite the

AT FULL LOAD AND ABOUT 25 PER CENT EXCESS AIR AT FURNACE OUTLET

burners increased slightly as the vanes were opened. This, of course, was accompanied by a decrease in absorption rate in this area. While the front-wall surface remains clean during these changes in vane opening, the heat absorbed by this surface decreased as the vanes were opened. The distribution of heat absorption in the side walls did not vary greatly, although there are some indications that the zones of relatively high absorption rates near the burners contain lower absorption rates at 50 per cent vane opening. Considering the distribution of heat absorption over the height of the furnace, it was found that at the 6-ft elevation there was little change in the average heat-absorption rates. However, between the 6-ft and 35-ft elevation, the heat absorption varied considerably for the different vane openings, apparently caused by the variations in ash coverage of the rear wall in this area. From elevation 35 ft to the top of the

furnace, the trends in absorption rates are the same for various vane openings, but the tests with the higher vane openings show lower absorption rates. The furnace heat-absorption efficiency decreased about 4 per cent as the vane openings were increased from 40 to 60 per cent.

(b) 100 per cent full load—17 per cent excess air (test Nos. 18 and 19): Again, it was found that the heat absorption in the front wall decreased as the vanes were opened, while the cleanliness in this area remained constant. The ash coverage of the rear wall did not vary appreciably between tests. The zones of relatively high heat absorption on the side walls near the burners did not change greatly as the vane openings were varied, but it did appear that the absorption rates found in these zones were reduced as the vane openings were increased. In studying the distribution of heat absorption over the height of the furnace, it

FIG. 27 FURNACE TUBE LEVEL AVERAGE ΔT -VARIATION WITH EXCESS AIR AT FULL LOAD AND 60 PER CENT SECONDARY-AIR VANE POSITIONFIG. 28 FURNACE TUBE LEVEL AVERAGE ΔT WITH VARIATIONS IN NET HEAT AVAILABLE TO FURNACE FOR NORMAL SECONDARY-AIR VANE POSITIONS AND ABOUT 25 PER CENT EXCESS AIR

was found that the trends obtained for both of these vane openings were the same but that slightly lower absorption rates were found over the height of the furnace with the higher vane opening. It was noted that there was little variation in absorption at the burner elevation, which indicates that the ash accumulation in this region and its variations were small on both of these tests. The furnace efficiency decreased about 2 to 3 per cent as the vanes were opened from 40 to 60 per cent.

(c) 100 per cent full load—30 per cent excess air (test Nos. 21 and 22): The heat absorbed by the front wall decreased as the vanes were opened. The absorption rates in the zones of relatively high absorption on the side walls decreased as the vanes were opened. The ash coverage of the rear wall opposite the burners apparently increased as the vanes were opened, causing a decrease in absorption rates in this area. The dis-

tribution of the heat absorption over the height of the furnace was not changed greatly as the vane openings were varied; On both tests it is indicated that ash coverage at the burner elevations caused a reduction in heat-absorption rates in this area. The furnace efficiency remained nearly constant as the vane openings were varied, since a decrease of only 1 per cent was shown as the vane openings were increased from 45 to 60 per cent.

(d) 75 per cent full load—25 per cent excess air (test Nos. 24 to 26, inclusive): The heat absorbed by the front wall decreased when the vane openings were increased. The high absorption zones on the side walls did not appear to change significantly as the vane openings were varied. The distribution of heat absorption over the height of the furnace did not change greatly as the vane openings were varied although higher rates

FIG. 29 VARIATIONS OF FURNACE HEAT-ABSORPTION EFFICIENCY WITH NET HEAT INPUT TO FURNACE FOR THREE DIFFERENT SECONDARY-AIR VANE POSITIONS WITH EIGHT BURNERS IN SERVICE AND APPROXIMATELY 25 PER CENT EXCESS AIR AT FURNACE OUTLET

of absorption were found on the tests at the lower vane openings. The heat-absorption rates at the burner elevations were low on all of these tests, apparently owing to the ash coverage in this area. It is also possible that this ash was deposited on some of full-load tests and that the change in furnace rating was not sufficient to allow it to clean itself. Increasing the vane opening under these conditions caused a decrease in furnace heat-absorption efficiency of about 3 to 4 per cent.

(e) General: Summarizing the foregoing results, it is found that increasing the vane opening results in decreasing the heat

absorbed in the front wall and usually causes a reduction in absorption in the rear wall owing to an increase in ash coverage. The rate of heat absorption in those zones of relatively high absorption rates on the side walls near the burners usually decreases as the vanes are opened. The distribution of heat absorption over the height of the furnace does not vary greatly in any range of elevation other than in the vicinity of the burners, but lower absorption rates are found throughout the furnace as the vane openings are increased. The effect of varying vane opening on furnace heat-absorption efficiency at full load seems

FIG. 30 VARIATION OF FURNACE HEAT-ABSORPTION EFFICIENCY WITH SECONDARY-AIR VANE OPENING AT APPROXIMATELY 100 PER CENT FULL LOAD FOR THREE DIFFERENT EXCESS-AIR VALUES AT FURNACE OUTLET

FIG. 32 VARIATION OF FURNACE HEAT-ABSORPTION EFFICIENCY WITH SECONDARY-AIR VANE POSITION FOR APPROXIMATELY 75 PER CENT FULL LOAD WITH 25 PER CENT EXCESS AIR AT FURNACE OUTLET

to change depending upon the excess air used. At 17 and 25 per cent excess air, we found a decrease of approximately 2 to 4 per cent as the vanes were opened, but found only a slight decrease in efficiency as the vane opening was increased at 30 per cent excess air. The effect of vane openings on furnace efficiency seems to be slightly reduced as the furnace rating is reduced.

Effect of Varying Heat Input to Furnace. The effect of varying heat input was studied between the approximate range of 50 to 93 per cent full load at 25 per cent excess air at the furnace outlet with eight burners in service. The effect of this variable alone is probably best shown by comparing test Nos. 15, 25, and 27, where the secondary-air vane openings were 40, 35, and 30 per cent open, respectively. Other comparisons in the range

FIG. 31 VARIATION OF FURNACE HEAT-ABSORPTION EFFICIENCY WITH EXCESS AIR AT FURNACE OUTLET FOR THREE DIFFERENT SECONDARY-AIR VANE SETTINGS AT APPROXIMATELY 100 PER CENT FULL LOAD

of about 70 per cent to 93 per cent full load may also be made. Test Nos. 17 and 25 were run at 50 per cent vane opening, and test Nos. 16 and 26 were made at 60 to 65 per cent vane opening.

Comparing test Nos. 15, 24, and 27, it is found that the distribution of heat absorbed in the front wall does not vary greatly, regardless of the heat input, although, of course, it increases in amount as the heat input is increased. The location of the zones of higher absorption found on the side walls near the burners does not change greatly as the heat input is increased, but the rate of heat absorption in these zones increases. The rear wall is less affected by ash accumulation at the lower heat inputs with the result that it has a more uniform and nearly as great absorption at the lower loads as are obtained at the high load. In general, the isothermal diagrams become a little more spotted at 50 per cent full load.

Comparing the distribution over the height of the furnace, it is found that the general trends remain the same, except at the burner elevations. At full load, it is noted that there is a small reduction in the absorption in this particular area when comparing it to elevations both above and below this region. At about 70 per cent full load, there is a considerable reduction in absorption at the burner elevation, but it is felt that this is caused by ash coverage on the rear wall which was accumulated during some of the various operating conditions at full load and did not clean itself, thus distorting the true distribution at this load.

At 50 per cent load, it is found that the distribution of heat absorption over the height of the furnace is much more uniform than found under the preceding conditions and reaches a maximum at the burner elevation. This indicates that at 50 per cent load the distribution of heat absorption is not affected by ash coverage and that the ash coverage is negligible. The other tests show about the same results for the range in which they were investigated.

The furnace heat-absorption efficiency for test Nos. 15, 24, and 27 indicates that, as the heat input is increased in the range from 50 to 70 per cent full load, there is only a slight decrease in furnace efficiency, but that increasing the heat input in the range from 70 to 93 per cent causes an appreciable reduction in furnace efficiency (about 7 per cent). Comparing the other

tests at 50 and 60 per cent vane opening in the range from 70 to 93 per cent, the same results are noted.

Effect of Varying Excess Air at Furnace Outlet. The effect of varying excess air at the furnace outlet was studied at approximately full load in the range between 17 to 30 per cent. Test Nos. 15, 18, and 21 were all run with approximately 40 per cent secondary-air vane opening. Test Nos. 16, 19, and 22 were all run with 60 per cent vane opening. It is found that the distribution of heat absorption on the various furnace walls varies only a small amount as the excess air is increased, although there are some indications that the absorption rates in the rear wall are decreased as the excess air is increased, apparently due to an increase in ash coverage. The zones of high absorption on the side walls near the burners do not seem to vary significantly as the excess air is changed, although the rates of heat absorption found were a little higher at the low excess air.

In studying the distribution of heat absorption over the height of the furnace at 60 per cent vane opening, it is noted that from elevation 35 ft to the top of the furnace there is little change in distribution regardless of the amount of excess air used, but that considerable variations are found from the hopper throat up to the 35-ft elevation.

At 17 per cent excess air the heat-absorption rate reaches a maximum at the burner elevations. At 25 per cent excess air, the absorption rate is rather constant over this range of elevation. At 30 per cent excess air there is a considerable reduction in the heat absorption at the burner elevations, but the heat absorption is higher just under the burner elevations than is noted under the other conditions. These same general characteristics are noted in comparing the tests at 40 per cent secondary-air vane opening.

It was indicated that the furnace heat-absorption efficiency at 40 per cent vane opening decreased rather rapidly as the excess air was changed from 17 to 25 per cent, and then remained approximately constant as the excess air was increased from 25 to 30 per cent. It was also indicated that at 60 per cent vane opening the furnace efficiency decreased rapidly between 17 and 25 per cent excess air, and then increased slightly as the excess air was increased from 25 to 30 per cent. This indicates that, as the excess air is increased at constant vane opening from 17 to 25 per cent excess air, there is a reduction in furnace efficiency which can be recovered partially by increasing the excess air further. This might be caused by the increase in the angular velocity of the mixture leaving the burner throat. Both the study of variations of the amount of excess air and the study of variations in secondary-air vane opening seem to indicate that an increase in the angular velocity of the fuel mixture leaving the burner throats results in improving the mixing of the fuel and air and possibly increases the rate of combustion of the fuel particles. Thus it seems possible that the temperature of the flame envelope might be changed as well as its shape as the angular velocity of the fuel mixture is changed.

Effect of Various Combinations of Burners in Service at 50 Per Cent Full Load. Test Nos. 27 to 30, inclusive, were run at about 50 per cent full load with approximately 25 per cent excess air at the furnace outlet. Test No. 27 was run with all eight burners in service, Test No. 28 with only the four upper burners, Test No. 29 with only the four lower burners, and Test No. 30 with the two upper inside burners and the two lower outside burners in service. It was found that the distribution and amount of heat absorbed by the front wall did not vary greatly on any of these tests. The heat absorption by the rear wall did change considerably depending upon which burners were used. The absorption by this wall was much more uniform when all eight burners were used and also much less affected by ash coverage. It was found that the location of higher absorption rates on

the rear wall changed with the combinations of burners in service. They were located highest on the rear wall with the four upper burners in operation and lowest when the four lower burners were used. The zones of high absorption rates on the side walls near the burners did not vary greatly but yet tended to shift up and down, depending upon which burners were used. These zones contained the lowest absorption rates when all eight burners were used.

When studying the distribution of heat absorption over the height of the furnace for these tests, it was found that from the 35-ft elevation to the top of the furnace there was little change in distribution. However, from the ash-hopper throat up to the 35-ft elevation, the distribution was changed considerably for the various burner combinations. With the four lower burners in operation, the maximum absorption rates were found just below the lower burner elevations. With the four upper burners in operation, the maximum absorption rate was found at the elevation of these upper burners. When the two upper and two lower burners were used, the maximum heat-absorption rate was found to be less than those obtained with the other four burner combinations and spread over a wider range of elevation, reaching its maximum near the elevation of the lower burners. When eight burners were used, the absorption rate in this region was much lower and much more constant, reaching its maximum value at the elevation of the upper burners.

It was indicated that the lowest furnace efficiency was obtained with eight burners in operation and increased in the following order: four upper burners, four lower burners, and two upper and two lower burners. However, using the convection superheater as an indication of furnace efficiency, it was found that the four lower burner operation resulted in a higher furnace efficiency than was obtained with the two upper and two lower burner operation. It also seems that the difference in efficiency between four lower burner operation and two upper and two lower burner operation is too small to establish definitely by the ΔT -method, which is the more efficient.

CONCLUSIONS

Based upon the foregoing data and analysis of results, we have formed the following conclusions concerning the performance of this furnace under the operating conditions investigated:

1. Ash does not collect in sufficient quantities to affect the heat absorption by the furnace-wall surface at any location other than the area of the rear wall at the burner elevations, where there is a tendency to accumulate and shed ash under some of the operating conditions studied.

2. Considering the distribution of heat absorption over the height of the furnace, it is found that the average absorption rates are usually highest at the elevation just below the burners, although indications show that the maximum might be found at the burner elevations if it were not for the effect of ash coverage in this area. A second peak of higher absorption rates occurs at the elevation where the cross-sectional area of the furnace is reduced, near the top, by the rear-wall sloping section.

3. Variations in absorption rates for clean furnace surface throughout the furnace do not exceed a magnitude of 3 or 4 to 1. Zones of 60,000 to 75,000 Btu/(sq ft-hr) absorption rates exist in that area of the side walls near the burners, and relatively high rates of absorption occur in that area of the rear wall which forms part of the hopper throat at the bottom of the furnace under all of the operating conditions studied.

4. Opening the secondary air vanes, in the ranges studied, causes (a) a reduction in heat absorbed by the front walls; (b) an increase in ash accumulation on the rear wall opposite the burners, accompanied by a decrease in absorption in this area; (c) a reduction in absorption rates in the zones of higher absorption

on the side walls near the burners; (d) a decrease in absorption at the burner elevations and lower absorption rates throughout the furnace; and (e) a decrease in furnace efficiency, which varies with excess-air and heat-input conditions.

5 Increasing the excess air for combustion, in the range from 17 to 30 per cent, causes (a) a reduction in heat absorption at the burner elevations; (b) an increase in ash coverage in that area of the rear wall directly opposite the burners; and (c) a decrease in furnace heat-absorption efficiency with varying characteristics, depending upon which secondary-air vane opening is used.

6 Variations in the combination of burners in service, at 50 per cent full load, causes (a) changes in the ash coverage on the rear-wall area opposite the burners; (b) variations in the average absorption rates at the burner elevations, and the locations of higher absorption zones shift up and down, depending upon the burners used; and (c) variations in furnace heat-absorption efficiency in the range of approximately 5 per cent.

7 The ΔT -method provides a good means of determining the distribution of heat absorption in the furnace and many of its inherent errors apparently cancel themselves in the determination of the furnace heat-absorption efficiency. However, it is recommended that wherever furnace efficiency is concerned, the reader should also refer to the heat-balance data contained in Part II of the investigation at Paddy's Run Station.

The data, diagrams, and curves which have been included in this paper should be of considerable assistance to the furnace designer and operator in predicting performance characteristics of similar furnaces, although it must be recognized that other operating variables, such as different characteristics of the fuel fired, may revise or modify some of the results which have been found.

ACKNOWLEDGMENTS

The authors wish to express their appreciation for the assistance rendered by the following in making this extensive investigation possible:

The ASME Special Research Committee on Furnace Performance Factors for the opportunity of participating in this investigation.

The officials of the Louisville Gas and Electric Company, Mr. A. G. Rosenbaum, General Superintendent, and Mr. F. B. Tetzel, Superintendent of Power Production, who made the No. 3 unit at Paddy's Run Station available to the committee for testing,

and co-operated with the committee in every possible way throughout the extended test program.

Mr. John Blizzard, Mr. Martin Frisch, Mr. A. R. Mumford, and Mr. Fred Ely for their very helpful criticisms and suggestions.

The personnel of Paddy's Run Station of the Louisville Gas and Electric Company: Mr. J. D. Brecker, Plant Engineer; Mr. S. P. Connor, Assistant Plant Engineer; Mr. H. C. Scherffleus, Economy Engineer; and their assistants who gave capable and willing assistance in accomplishing the test program.

The Combustion Research Section of the U. S. Bureau of Mines whose contributions on this test project have been outstanding.

The members of the Service Department, Steam Division and Research Department of the Foster Wheeler Corporation, who gave generously of their time and experience in the running of tests and analysis of results.

Part II. Furnace Heat-Absorption Efficiency as Shown by Temperature and Composition of Gases Leaving the Furnace

By R. C. COREY¹ AND PAUL COHEN,² PITTSBURGH, PA.

This paper is part of the second of a series of formal reports on investigations of heat absorption and distribution of heat transfer in representative pulverized-coal-fired boiler furnaces, sponsored by the ASME Special Research Committee on Furnace Performance Factors. The results are presented of fifteen determinations of heat absorption in the furnace of a 640,000 lb per hr boiler with horizontal firing, operating at 950 psig and 900 F at the superheater outlet. The effect on furnace heat-absorption efficiency is shown for variation of (a) the heat available in the furnace, (b) the excess air, (c) the setting of the secondary-air vanes of the turbulent burners, and (d), at low loads, the number and location of the burners used. Detailed data are given for the distribution of excess air and gas temperature at the furnace outlet. The heat-absorption data are analyzed in terms of radiation heat transfer, and the significance of flame location, volume, and shape is discussed.

INTRODUCTION

THIS paper presents the results of determinations of the heat-absorption efficiency of a central-station, pulverized-coal-fired, steam-boiler furnace, for a variety of operating conditions. It is a part of the report of the second³ of a series of comprehensive investigations of heat transfer in boiler furnaces by the Special Research Committee on Furnace Performance Factors of the Society. The unit studied in this second investigation is boiler No. 3, Paddy's Run Station, Louisville Gas & Electric Company, Louisville, Ky., a single-drum boiler, with a dry-bottom furnace, fired from the front wall with eight horizontal turbulent burners arranged in two rows and rated at 640,000 lb of steam per hr at 950 psig and 900 F at the superheater outlet.

The investigation of this unit by the committee consisted of

two parts, namely, determination of the total heat absorption in the furnace, which is the subject of this paper, and determination of the distribution of heat absorption in the furnace, the subject of another paper of this symposium. The furnace heat-absorption tests were made by the Combustion Research Section of the Bureau of Mines, concurrently with the other studies, as part of the Bureau of Mines co-operative research program with the committee to study the effect of ash and slag on furnace performance.

Fifteen tests were made to determine the effect on furnace heat absorption of variations of load, excess air, adjustment of the turbulent burners, and, at low loads, the number and location of the burners used. The heat absorption is defined as the heat transferred by convection to the furnace walls, not including the screen, and the heat transferred by radiation to the furnace walls, including the screen. With slight modification, the test procedure is that of Method *b* of the ASME Test Code for Stationary Steam-Generating Units. The heat absorption in the furnace is obtained as the difference between the net heat available in the furnace (the low heat value of the fuel fired, corrected for unburned combustible, plus the sensible heat in the air used for combustion) and the sensible heat in the furnace-outlet gases and the refuse, and the heat transferred from the furnace casing.

The sensible heat in the furnace-outlet gas was calculated from the temperature and composition determined by techniques appropriate for furnace testing.⁴ Measurements were made at a number of positions approximating the furnace outlet within the limitations of the available means of access to the furnace. Because of the significance of the distribution of the temperature and composition of the gases at the furnace outlet, the complete test data are tabulated in the paper.

METHODS OF TEST AND CALCULATION

Description of Furnace. Fig. 1 is a sectional side elevation of the boiler, showing the general arrangement of the components. The furnace is 78 ft high from the top of the hopper to the center line of the drum, 31 ft 0 1/2 in. wide between side-wall tubes, 24 ft 3 in. deep, and the volume is 47,100 cu ft. All furnace walls consist of 3-in.-OD tubes on 3 1/2-in. centers, backed by tile. The front portion of the furnace roof is formed by the direct continuation of the front-wall tubes, and the rear portion of the roof is formed by the back-wall tubes bent forward and covered on the outside with a tile baffle. The slag screen is formed from the back-wall tubes expanded into four rows of tubes with a 9-in. center-to-center spacing between rows and a 13-in. center-to-

FIG. 1 SECTIONAL SIDE ELEVATION OF BOILER NO. 3, PADDY'S RUN STATION

center spacing between lanes. The front row of screen tubes is 8 ft 11 1/2 in. from the front-wall tubes, center-to-center distance. The furnace outlet is 18 ft 4 in. high and 30 ft 9 1/2 in. wide. The area of projected radiant-heating surface in the furnace is 8884 sq ft, including the developed area of the furnace outlet, 564 sq ft.

The furnace is fired with eight inter-vane burners in the front wall, arranged in two rows of four each with center lines 4 ft 4 in. and 10 ft 4 in. above the top of the hopper, respectively. Fuel is supplied by two ball-mill pulverizers equipped with two exhausters each. The north mill fires the two inner upper burners and the two outer lower burners, and the south mill, the other four burners. Forced-draft fans, induced-draft fans, and regenerative air heaters are all in duplicate and arranged at the back of the unit. Interconnecting dampers permit operation at low loads with but one set of fans and air heater, but, in the tests, both sets of auxiliaries were always used to assure the best balance in the furnace and beyond.

Location of Test Points. After consideration of the available access doors, it was decided to make all measurements from six lancing doors at the front of the furnace, 64 ft above the top of the hopper. A large proportion of the furnace outlet could be reached by inserting a 14-ft water-cooled high-velocity thermocouple probe through these doors and swinging the probe at various angles from the horizontal. Thirty sampling positions

were used in the tests, arranged in six columns (A, B, C, D, E, and F), corresponding to the location of the lancing doors in the front wall, each column having five sampling points, designated +6, +3, 0, -3, and -6, which are approximate vertical distances in feet from the midplane of the furnace outlet. The actual sampling points were 6 in. in front of the screen at the elevations shown. The resulting distribution of sampling points is shown in Fig. 2, a map of the developed furnace-outlet area, drawn to scale. The furnace outlet is also shown by the heavy line in Fig. 1.

To facilitate manipulation of the long and heavy water-cooled thermocouple holder and to provide reproducibility of the location of the sampling positions, a special insert was built for the lancing doors, which provided means for convenient and accurate manipulation of the probe and also permitted rather complete sealing of the door during sampling, with asbestos-board plates. Fig. 3 gives the general details of this special insert.

Instrumentation and Analyses. The temperature and composition of the gas at the furnace outlet were determined with instrumentation and technique previously described.⁴ The following brief review will be helpful:

(a) The temperature of the gas at the furnace outlet was determined with high-velocity thermocouples (platinum, 10 per cent rhodium-platinum elements), using two new designs of multiple shields shown as types E and G in Fig. 4. Direct compari-

son between the shields, and the B&W MHVT (multiple high-velocity thermocouple), also shown in Fig. 4, were made in the subject furnace. The corrections of the observed temperatures, to the B&W MHVT basis were small, 30 F and 40 F for types E and G, respectively, at 2000 deg F. Because of the short length of the Pt Rh-Pt couple and the high gas-flow rates used in the probes, the temperature of the junction between the lead wire and couple in the probe exceeded the value at which the two were matched, and an additional minor correction was required because of the difference in thermoelectrical properties of the couple and lead wire. The emf of the thermocouples was recorded with a high-speed electronic potentiometer recorder equipped with a 1-hr clock, and representative average values of the temperature of the gas at a sampling point could be obtained from records of $1/2$ to 1 min duration.

(b) Gas analyses and temperature measurements were made simultaneously by connecting a Bailey oxygen recorder, with a 1-hr clock, in series with the aspirating system of the high-velocity thermocouple. Routine complete analysis of the gases being sampled by the Bailey oxygen recorder served both to check the calibration of the Bailey oxygen recorder and to correlate the

oxygen content of the furnace-outlet gas with that of the other gas constituents. As with the temperature measurements, significant average values for the oxygen content of the gas at a sampling point could be obtained from records of $1/2$ to 1 min duration.

(c) Except for analysis of the flue gas entering the air heaters, for which the technique just described was employed, all other required observations were made with plant instrumentation. The temperatures of the flue gas and air entering and leaving the air heaters were recorded at the control board by two resistance thermometers properly situated in each duct at which measurements were made. Coal feed rates were ascertained by recording at regular intervals the time and the number of the trip at each of the four coal scales (two for each mill). Increments of the coal were taken at the scales, following ASTM specifications, and were stored during the test in 10-gal milk pails. The samples were reduced to approximately 35 lb and shipped to Pittsburgh in sealed cans for analysis by the Coal Analysis Section of the Bureau of Mines.

The quantity of fly ash in the gas entering the Cottrell precipitators was determined by the staff of the Louisville Gas & Electric Company, using the methods of the Research Corporation and with equipment supplied by the latter company. The fly ash was analyzed by the Coal Analysis Section of the Bureau of Mines.

The humidity of the air was determined by sling psychrometer at the F.D. fan inlet.

General Test Procedure. The superheaters and air heaters were blown routinely before each test, and, as required, excess slag deposits on the furnace screen were removed by hand lancing. The necessary burner adjustments were made, the load was adjusted to the desired value, and the fans were balanced as closely as possible. A preliminary analysis of the furnace gas was made through door C, and the air flow was then adjusted accordingly to give the desired excess air at the furnace outlet. Because of occasional nonuniformity of the gas at the furnace outlet, this procedure involved some guesswork and did not always yield the desired excess air. Coal-scale readings were started as soon as the unit was stabilized, and the test continued for a period of about 4 hr, the time necessary to make a complete set of all the

FIG. 2 DISTRIBUTION OF SAMPLING POINTS AT FURNACE OUTLET

FIG. 3 LANCING-DOOR INSERT FOR SUPPORTING WATER-COOLED HIGH-VELOCITY THERMOCOUPLE PROBE

FIG. 4 RADIATION SHIELDS FOR HIGH-VELOCITY THERMOCOUPLE

measurements required for the committee's investigation. The survey at the furnace outlet usually required less than 3 hr.

Methods of Calculation. (a) *Temperature and Gas-Composition Data.* Because the sampling points are quite uniformly distributed over the furnace-outlet area, simple numerical averages were calculated of the observed temperature and oxygen-concentration data. These averages, with appropriate corrections, were then used in all subsequent calculations, as previous considerations⁴ had shown that more rigorous treatment can rarely be justified.

(b) *Furnace Heat Balance.* The heat absorption in the furnace is calculated as the difference between the net heat available in the furnace and the heat lost from the furnace in the products of combustion, and by radiation and convection from the furnace casing. The net heat available in the furnace is the sum of the low-heat value of the fuel fired (corrected for unburned combustible) and the sensible heat in the preheated air. Combustible losses were calculated from the analysis of the fly ash, the fly ash concentration, and the calculated quantities of the gases at the entrance to the Cottrell precipitator. The sensible heat in the preheated air was calculated from a heat balance on the air heaters, employing the known temperatures of the gas and air streams entering and leaving the air heaters, the average composition of the gas entering the air heater, and an assumed value for the air leakage in the preheater equal to 5 per cent by weight of the gas entering the heater.⁵

The enthalpy of the furnace-outlet gas was calculated from the quantities of the respective gases at the furnace outlet (computed from the gas composition and corrected fuel analysis), and the heat contents of the individual gases at the average temperature of the furnace-outlet gas, obtained from the tables of Heck.⁶

For the purpose of these calculations it was assumed that all the ash left the furnace at the temperature of the gases; the heat content was calculated using a mean specific heat of 0.27 Btu per lb deg F. The heat loss from the furnace casing was taken as one half that of the entire unit as given by the ABMA Standard Radiation Loss Chart.

RESULTS OF TESTS

Description of Tests. The operating data and the results obtained in the fifteen tests are summarized in Table 1. The tests are divided into three groups; group 1, consisting of eight tests at full load, numbers 15, 15A, 16, 17, 18, 19, 21, and 22, was made to determine the effect on furnace heat absorption of variations of excess air and secondary-air vane settings at the test load. Group 2, consisting of three tests at three-quarters load, numbers 24, 25, and 26, was made to determine the effect of secondary-air vane settings at the test load; and group 3, consisting of four tests at half-load, numbers 27, 28, 29, and 30, was made to determine the effect of the number and location of the burners, at the test load. The fuel burned in these tests consisted of a quite uniform mixture of high-volatile C West Kentucky coals. There was little variation in coal composition from test to test, as shown in Table 1.

Temperature and Gas Composition at the Furnace Outlet. Of considerable interest, in addition to the calculated furnace heat absorption, is the distribution of the temperature and composition of the gases at the furnace outlet. These data are given in Tables 2 and 3, respectively. The temperature data in Table 2 are the values observed with the shields used in the particular test; for the heat-absorption calculations, the averages of these values

were corrected to the B&W MHVT basis and for lead-junction errors as shown in Table 4. The gas compositions in Table 3 are expressed as per cent excess air, as possibly affording more familiar and representative values than the oxygen percentages actually observed. A recent discussion⁴ showed that these values are quite representative of the average conditions for which the tests were made, and, when plotted on a map of the furnace outlet, yield consistent and significant distribution patterns. This is illustrated in Figs. 5 and 6, which are distribution plots of the temperature and composition of the gas at the furnace outlet, respectively, for test 22.

These plots demonstrate some of the outstanding characteristics of the type of firing used in the subject boiler. One of these is the considerable spread of temperature of the gases at the furnace outlet, compared to the spread in gas composition. Thus the gas at sampling point D+6, excess air 33.7 per cent, leaves the furnace at 1920 F, whereas the gas at sampling point D-6, excess air 32.9 per cent, or practically the same as that of the gas at D+6, leaves the furnace at 2320 F. It is evident that the coal-air mixtures from which these streams of gases originated were quite similar, but had considerably different experiences in traversing the furnace volume from the burner to the furnace outlet. The gas leaving the furnace at D+6 has lost considerably more heat to the walls than the gas leaving the furnace at D-6; this is probably due to a longer residence time in the furnace, and probably a lower average velocity in the furnace. This is in accord with visual observations of the velocity of the gases leaving

Additional data are available on fly ash analysis and distribution, and humidity of combustion air. For tests 18, 19, 24, 25, 26, the forms of sulfur and carbonate in coal were determined, as well as the ash cone softening temperatures in an oxidizing atmosphere.

a/ Uncorrected; for corrections see Table 4.

b/ For test conditions, see Table 1.

c/ For location at furnace outlet, see Figure 2.

d/ Data not taken; extrapolated value

the furnace, being greatest at the bottom of the outlet and lowest at the top. The effect of this behavior on the radiation heat transfer in the furnace will be considered in a later part of this paper.

Detailed distribution data of the type shown in Figs. 5 and 6 assist in understanding ash deposition and slagging of the screen and superheater. The wide spread in temperatures at the furnace outlet demonstrates the readiness with which excessive temperatures can exist, even though the mean value is less than some assumed safe limit.

The distribution plots for the other tests are not given, but may readily be constructed from the data in Tables 2 and 3.

Furnace Heat Absorption. For reader reference, a condensed summary of the test conditions and results is presented in Table 5 in which each test is given a reference letter. In Fig. 7 the observed furnace heat-absorption efficiency has been plotted against excess air for the various combinations of the other test variables. The furnace heat-absorption efficiency is used in Fig. 7 because it is less sensitive than furnace heat absorption to the unavoidable variations in the net heat available in the tests at each particular boiler load. Lines have been drawn in Fig. 7 indicating the effect of excess air on furnace heat-absorption efficiency, for the various settings of the secondary-air vanes at full and three-quarters load; and for the various locations and number of burners used, at half-load. At full load there are enough experimental points to establish these lines, and, except for points B and C, tests 15A and 16, respectively, the relationships are quite definite. At three-quarters and half-load, the variations of furnace heat-absorption efficiency with excess air can only be inferred; these lines (dashed) have been given successively lower slopes as the load decreases, in accord with the behavior found in another furnace.³

TABLE 4 CORRECTIONS OF OBSERVED AVERAGE TEMPERATURE TO B&W MHV BASIS, ASME FURNACE HEAT-ABSORPTION TESTS, BOILER NO. 3, PADDY'S RUN STATION, LOUISVILLE GAS & ELECTRIC COMPANY, OCTOBER 20-30, 1948.

a/ For test conditions, see Table 1.

b/ For location at furnace outlet, see Figure 2.

From Fig. 7 it will be noted that the effect of secondary-air vane setting is quite pronounced at full load; a change in the setting from 60 to 40 per cent open at 17 per cent excess air increases the furnace heat-absorption efficiency from 44.1 to 46.8 per cent. Also, the effect of secondary-air vane setting is considerably reduced at three-quarters load; a change in the setting from 65 to 35 per cent open, at 23 per cent excess air, increases the furnace heat-absorption efficiency by only 0.6 per cent. The effect at half-load may be presumed to be negligible. Further, the effect of secondary-air vane setting at full load appears to be quite independent of excess air, the change in furnace heat-absorption efficiency due to change in secondary-air vane setting from 60 to 40 per cent open being 2.7, 2.7, and 2.7 per cent at 17, 23, and 29 per cent excess air, respectively. Similarly, the effect of change of excess air, at constant secondary-air vane opening, appears to be independent of the opening of the secondary-air vanes. Figs. 8 and 9 are similar plots of the experimental results, showing the furnace heat absorption and the average temperature of the furnace-outlet gases, respectively.

FIG. 8 FURNACE HEAT ABSORPTION AS AFFECTED BY EXCESS AIR, NET HEAT AVAILABLE IN FURNACE, SECONDARY-AIR VANE SETTINGS, AND NUMBER AND LOCATION OF BURNERS USED

FIG. 9 AVERAGE TEMPERATURE OF FURNACE-OUTLET GAS AS AFFECTED BY EXCESS AIR, NET HEAT AVAILABLE IN FURNACE, SECONDARY-AIR VANE SETTINGS, AND NUMBER AND LOCATION OF BURNERS USED

(O, Eight burners, ●, four burners; letter designates test, see Table 5; number after letter is secondary-air vane opening, per cent.)

The rather complicated relationships between the variables cannot be represented simply, and a number of curves are required. Fig. 10 shows the effect of net heat available in the furnace on furnace heat absorption for three different values for the excess air at the furnace outlet, all at one setting of the secondary-air vanes, 40 per cent open. The curve for 23 per cent excess air is drawn with a full line, because all the necessary data are available. The effect of excess air is known only at full loads; therefore the curves for 17 and 29 per cent excess air are drawn with dashed lines.

The upper part of Fig. 10 shows the effect of secondary-air vane opening. The corrections to the furnace heat absorption for secondary-air vane settings other than 40 per cent open are plotted as a function of net heat available in the furnace for secondary-air vane openings of 50 and 60 per cent. Since the effect of secondary-air vane openings is independent of excess air, at least at high loads, Fig. 8, only one set of correction curves is required.

The relationships shown in Fig. 10 apply only to operation

FIG. 10 FURNACE-PERFORMANCE CHARACTERISTICS

with eight burners. The effect of operation with four burners is shown on the lower part of the plot by the additional points representing the results for various combinations of the burners.

The qualitative relationship of all the variables is best conveyed by the isometric three-variable plot in Fig. 11, which readily shows the decrease in furnace heat absorption with increased excess air at all loads, the almost linear increase in furnace heat absorption with increase in net heat available in the furnace, between 47 and 88 kB per hr and ft², and the decrease of furnace heat absorption with increase in the opening of the secondary-air vanes, this effect being independent of excess air, but increasing rapidly with net heat available in the furnace, between 66 and 88 kB per hr and ft².

CORRELATION OF TEST RESULTS

The correlation of the test conditions and results so far given is purely empirical, without reference to the mechanism for heat transfer in the furnace. The information presented, though as comprehensive as the data on which it is based, nevertheless lacks generality because no account has been taken of the fundamental processes involved. Because of the complexity of the problem,

FIG. 11 THREE-VARIABLE REPRESENTATION OF FURNACE PERFORMANCE CHARACTERISTICS FOR EIGHT-BURNER OPERATION

progress in fundamental analysis has been slow, and confined largely to semiempirical correlations based either on the average temperature of the gases at the furnace outlet,^{7,8} or on a radiant mean temperature between the adiabatic temperature and the temperature of the gases leaving the furnace.⁹ Of these procedures the first is more convenient, and is applied to the data of this investigation in Fig. 12 in which the furnace heat absorption, kB per hr and ft², has been plotted against the fourth power of the average temperature of the gases leaving the furnace, deg R; the letter and point symbols correspond to Table 5. For comparison, line Z-Z shows the calculated black-body radiation from a source at the average temperature of the furnace-outlet gas, to the furnace walls at a constant temperature. In view of the cleanliness of the furnace walls, the latter temperature has been taken as 1050 R.

It will be seen that the unit heat transfer, based on the heat-receiving surface, is considerably less than that of a black body at the temperature of the furnace outlet gas, line Z-Z. Expressed in terms of an equivalent gray body at the temperature of the furnace-outlet gases, the heat transfer corresponds to that from a source with an emissivity of about 0.7, for the low-load tests and decreasing at high loads. It is further evident that if the correlation had been based on a radiation mean temperature, according to Blizard,⁹ the apparent emissivity of the source would be still lower. For one test at high load an approximate value of 0.28 was calculated for the apparent emissivity of the source on this basis. This is in sharp contrast to the high emissivities predicted from the work of Sherman¹⁰ for flames having the dimen-

sions of the subject furnace. As an example, Sherman predicted that even after combustion was essentially complete, the gas and suspended ash from Illinois coal would have total emissivities of 0.83 and 0.97 for 12 and 20-ft thicknesses, respectively.

The source of this discrepancy is found readily. The high-temperature gases do not fill the entire furnace volume, and not only is the exposed area of the radiation source less than that of the heat-receiving surface on which the unit heat transfer is calculated, but the mean beam lengths for radiation probably are considerably lower than would be calculated from the furnace dimensions. The ratio of area of flame to area of wall may be estimated as follows: As a first approximation, assuming wall emissivity of unity and flame emissivity equal to flame absorptivity, the net radiation heat transfer from flame to furnace walls, Btu per hr, may be written as

$$Q = \sigma \epsilon_F A_F (T_F^4 - T_W^4)$$

The subscripts *F* and *W* denote the flame and furnace wall, respectively, and

σ = radiation constant

A = area (of envelope for flame; of projected area for wall surface)

T = radiant mean temperature, abs

ϵ = emissivity

This equation may be rewritten as

$$Q = \sigma A_W \epsilon_F \frac{A_F}{A_W} (T_F^4 - T_W^4)$$

in which the product $\epsilon_F (A_F/A_W)$ may be considered an apparent emissivity of the flame, ϵ_F' , calculated from heat transfer per unit wall area, A_W . From an assumed value of true mean emissivity of the flame, $\epsilon_F = 0.9$, and a value of 0.28 for ϵ_F' previously calculated for one of the high-load tests, A_F/A_W may be obtained as the ratio of $\epsilon_F'/\epsilon_F = 0.28/0.9 = 0.31$. So low an indicated area of the flame, and therefore its volume, must include a significant effect of decreased true mean flame emissivity arising from smaller mean beam lengths, and the true value of A_F/A_W is undoubtedly somewhat higher than the value of 0.31 calculated. For the purposes of the present argument, no further refinement of the calculation is warranted.

Somewhat similar considerations were applied by Mumford and Bice¹¹ to the analysis of the effect of tilting the burner in a tangentially fired furnace previously studied by the committee. They concluded that multiplication of the observed rates of heat transfer for different inclination of the burners by the ratios of area of heat-receiving surface to area of flame envelope would have brought all the data into line. No estimate was made by them of the apparent emissivity of the flame, but the unit heat transfer based on the average temperature of the furnace-outlet gas was higher in the tangentially fired furnace than in the subject furnace, indicating that the apparent emissivities were higher.

This discussion has of necessity been only semiquantitative, and has undoubtedly exaggerated the true picture; for instance, the flame never achieves the adiabatic temperature. Also, only the general level of heat transfer has been considered; interpretation of the effect of burner adjustments on heat transfer at constant load is still required. So far it can only be concluded that the heat transfer in the furnace is considerably less than theoretically achievable levels.

FIG. 12 CORRELATION OF HEAT TRANSFER IN FURNACE WITH FOURTH POWER OF ABSOLUTE TEMPERATURE OF GASES AT FURNACE OUTLET

(O, Eight burners; ●, four burners; letter designates test, see Table 5.)

As previously noted, the gases at the furnace outlet display a characteristic temperature distribution which has been attributed to varying velocities of the respective portions of the gas stream in traversing the furnace volume. One of the possible means by which the setting of the secondary-air vanes may affect heat transfer in the furnace is by changing the velocity-distribution patterns in the furnace. That this probably does not occur, however, is seen from examination of the temperature-distribution data. For example, in both tests 18, and 19, 17 per cent excess air, and 40 and 60 per cent secondary-air vane openings, respectively, the average deviation of the temperature of the gases at the furnace outlet from their mean is 150 F. Thus if the distribution of temperature at the furnace outlet is taken as a criterion, the change in burner vane settings does not affect appreciably the velocity distribution of the gases in the furnace. The effect of secondary-air vane settings must be sought in the delayed combustion which occurs at high secondary-air vane openings. Under these conditions heat release is delayed, and thus radiation is decreased, compared to the turbulent bushy flame conditions obtained with lower secondary-air vane openings.

At the lower burning rates, the temperature and the velocity of the gas leaving the furnace are more uniform, as would be expected, because the total residence time of the gases in the furnace is greater. Similarly, because the percentage heat absorption is greater at low loads, the effect of burner adjustments on heat absorption is less pronounced.

Another factor, which should be considered as affecting the temperature distribution at the furnace outlet, is the tendency for ash deposits to be heavier on the rear than on the front wall of the unit, due to the flame-path characteristics. Thus the insulating effect of the ash would produce higher gas temperatures along the rear than along the front wall, and any temperature gradient at the furnace outlet caused by higher gas velocity along the rear wall, which was discussed previously, would be increased further.

The unique characteristics of each of the different methods of firing pulverized coal have long been recognized and need no emphasis here. Indeed, they form an essential basis for the design of the test program of the Furnace Performance Factors Committee. The important fact brought out by the results of this investigation is that detailed consideration must be given to burner location, flame shape, and volume, and all other factors which affect flame radiation, if a rational basis is to be found for predicting the heat absorption in boiler furnaces. The problem is tremendously complicated, and special attention must be given to these details to obtain basic generalizations.

SUMMARY AND CONCLUSIONS

The absorption of heat in the furnace of the Paddy's Run boiler was measured to provide basic performance data and to determine the relationship between the rate of heat transfer and the observed temperature drop across the furnace-wall tubes. The furnace heat absorption was determined as the difference between the heat input to the furnace, corrected for losses, and the sensible heat in the furnace-outlet gas obtained from measurements of the temperature and composition employing techniques appropriate for furnace testing. The effect on furnace heat absorption of load, excess air, burner setting, and, at low loads, the number and location of the burners, was studied in a series of fifteen tests.

In all tests, the temperature of the gas at the furnace outlet varied considerably with position, being highest at the bottom and lowest at the top. At full load, the spread in temperature exceeded 500 F; at lower loads the spread was somewhat less. In contrast, the composition of the gas at the furnace outlet was considerably more uniform than the temperature. There was little variation of gas composition in any of the tests from the top to the bottom of the outlet, but occasionally nonuniform distribution from side to side. In such cases the excess air was always highest on the left or south side of the furnace. From these observations it is concluded that the variations of the temperature of the gas with position at the outlet originated from variations in the velocity of the gas streams in the furnace. Visual observations of the gas streams did indicate that the velocity of the gas was highest at the bottom of the outlet and decreased toward the top of the outlet. Because of lack of suitable access, no velocity measurements were made to check these observations.

At full load, the furnace heat-absorption efficiency decreased with both increase of excess air, and opening of the secondary-air vane settings. The effect of excess air was independent of the secondary-air vane setting, and the effect of secondary-air vane setting was independent of excess air, over the range of the variables studied. Thus the furnace heat-absorption efficiency decreased about 2.7 per cent for an increase in secondary-air vane opening from 40 to 60 per cent, and decreased about 2.8 per cent for an increase in excess air from 17 to 29 per cent. The corresponding changes in the average temperature of the gases leaving the furnace were about 75 and 30 F, respectively.

At three-quarter load, the furnace heat-absorption efficiency decreased about 0.6 per cent for an increase in secondary-air vane opening from 35 to 65 per cent. The effect of excess air was not determined at this load.

At half-load, only the effect of the number and location of the burners was studied. With eight burners, the secondary-air vanes had to be set at 30 per cent open for good operation; with four burners, the secondary-air vane settings were 50 per cent open. The furnace heat-absorption efficiency was highest when the four lower burners were used; was 0.6 per cent lower when the

four upper burners were used; 1.9 per cent lower when all eight burners were used; and about 0.4 per cent lower when the 2 upper inner and 2 lower outer burners were used. The over-all variation in the average temperature of the gases leaving the furnace for the four combinations of burners was about 75 F.

For otherwise constant conditions, furnace heat absorption increases and furnace heat-absorption efficiency decreases as the heat available in the furnace increases. With eight burners, 40 per cent secondary-air vane opening and 23 per cent excess air, the heat absorption increases almost linearly from about 24 kB per hr and sq ft, at 47 kB per hr and sq ft heat available, to about 40 kB per hr and sq ft at 88 kB per hr and sq ft heat available in the furnace. The corresponding furnace heat-absorption efficiencies are approximately 52 and 45 per cent, respectively. The corresponding average temperatures of the gases leaving the furnace were 1755 and 2020 F, respectively.

At low load, the heat transfer in the furnace corresponded to that by radiation from a body having the area of the heat-receiving surface, the average temperature of the furnace-outlet gas, and an emissivity of 0.67. At higher loads, the apparent emissivity decreased. Analysis of the test results indicates that the area of the envelope of hot gases in the furnace must be considerably less than that of the heat-receiving surfaces. A ratio of 0.31, which is probably somewhat low, was calculated for full-load conditions, on the assumption that the coal is burned instantaneously. This, however, is evidently not the case. Indeed, the effect of burner secondary-air vane settings on furnace heat absorption can best be interpreted in terms of the effect on the rate of combustion of the coal.

This investigation has provided detailed knowledge of the properties of the gas leaving the furnace, and of furnace performance for a wide range of significant operating variables. Although the heat-transfer process in the furnace has not been evaluated quantitatively, a beginning has been made toward better understanding of this basic aspect of the problem of furnace performance.

ACKNOWLEDGMENTS

The authors gratefully acknowledge, with appreciation and thanks, the contributions to this investigation made by the following:

The Special Research Committee on Furnace Performance Factors of The American Society of Mechanical Engineers, for the opportunity to participate in this work, and the individual committee members for advice and help whenever required.

Dr. A. C. Fieldner, Chief, Fuels and Explosives Division, and Dr. R. L. Brown, Chief, Coal Branch, Bureau of Mines, who authorized the work and made many helpful suggestions.

The engineers and assistants of the Combustion Research Section: Messrs. J. W. Myers, J. Jonakin, C. H. Schwartz, J. J. Pfeiffer, G. Kollar, and H. Perry, who capably made the difficult tests that form the basis for this paper.

The officials of the Louisville Gas & Electric Company: A. G. Rosenbaum, Superintendent of Steam Power, Fred Tetzl, Assistant Superintendent of Steam Power, and J. D. Brecher, Plant Engineer, Paddy's Run Station, and their staffs, for willing and able assistance in the arrangement of the tests.

The Bailey Meter Company, for the loan of a recording oxygen meter.

Mr. Fred Ely of the Research and Development Division, Babcock & Wilcox Company, for the loan of a high-speed recording potentiometer.

Furnace Heat Absorption in Paddy's Run Pulverized-Coal-Fired Steam Generator, Using Turbulent Burners, Louisville, Ky.

Part III. Comparison and Correlation of the Results of Furnace Heat-Absorption Investigation

BY H. H. HEMENWAY¹ AND R. I. WHEATER,² NEW YORK, N. Y.

In this paper, the results of the two companion papers (Parts I³ and II⁴) are compared. Some of the possible sources of error are noted. Slightly revised calculated results are obtained by taking weighted averages of the data. The revised results are examined to determine which tests are the most dependable. An equation showing the relationship between furnace exit-gas temperature and furnace heat-absorption rate for a fixed burner adjustment is developed. From the revised results the effect of various factors on furnace performance is shown.

INTRODUCTION

THIS is the third of three papers presenting the results of investigations of furnace performance in the pulverized-coal-fired boiler No. 3 at Paddy's Run. These investigations were conducted under the sponsorship of the ASME Special Research Committee on Furnace Performance Factors. The first paper, Part I,³ of this series presents results and analyses of the data obtained by measuring the furnace face temperatures of waterwall tubes. The second paper, Part II,⁴ of this series presents the results and analyses of the data obtained by measuring the temperature and composition of the gas leaving the furnace and entering the slag screen. This paper deals with the comparison and correlation of the data presented in the first two papers.

Part I and Part II adequately describe the arrangement and dimensions of the furnace tested, the methods of testing, the methods of calculation, and the results obtained by each method of testing. By means of the two methods of testing, which will be referred to herein as the ΔT -method and the heat-balance method, the average heat-absorption rate expressed as MKB/(hr) for each test was determined. In Fig. 1, which is a copy of Fig. 21 of Part I, the results obtained by both methods of

FIG. 1 COMPARISON OF FURNACE HEAT ABSORPTION, COMPUTED FROM WALL-TUBE ΔT -DATA WITH FURNACE HEAT ABSORPTION COMPUTED FROM FURNACE EXIT-GAS TRAVERSE (Number designates test.)

testing are compared, and an examination of this figure shows that except for a few of the full-load tests, the 45-deg equality line falls fairly well within the pattern of test points.

The heat-absorption rate per unit of furnace radiant projected area determined from the heat balance, divided by the average temperature difference between the furnace-tube face and saturated water temperature, ΔT , yields the average over-all heat-transfer coefficient U_o . In Fig. 2 U_o is plotted against ΔT . This figure shows that the average over-all heat-transfer coefficient of 1060 Btu/(hr) (F) (sq ft of projected area), which was assumed in Part I in the calculation of furnace heat absorption by the ΔT -method, does not differ greatly from the values obtained from the heat balance.

THE ΔT -METHOD

Some Sources of Error. The principal sources of error in the ΔT -method which are considered here are as follows:

- (a) Errors in measurement.
- (b) Errors in averaging.
- (c) Errors in the assumptions.

Errors in measurement include the errors in the instruments

FIG. 2 CORRELATION OF FURNACE WALL-TUBE OVER-ALL AVERAGE HEAT-TRANSFER COEFFICIENT WITH ΔT

which were used in the tests. In addition, they include errors which may have been introduced in the temperature measurements of the front face of the wall tubes by the fact that the thermocouple shield probably served as a shelf for ash deposit and the resulting insulating or shading effect caused the temperature of the couple to be lower than the temperature of the wall of the tube remote from the shield.

In Part I the average over-all ΔT was assumed to be the arithmetic average of the ΔT -values for each live furnace-face thermocouple. Eight of the 128 thermocouples were dead and hence were not included in the averaging. The thermocouples could not be installed at uniform intervals, and none was installed on the rear wall roof or the slag screen. Thus there are reasons to suppose that the use of simple arithmetic averaging introduced some error in the results. In addition, since only one set of readings was taken during each 30-min period, the average value over this period may have differed slightly from the single value recorded owing to the small variations caused by operation with automatic controls.

In making the calculations it was assumed that the average tube-wall thickness at the thermocouple was 0.238 in., that the tube-wall conductivity was 348 (Btu) (in.)/(sq ft) (hr) (F), and that the heat-transfer coefficient from the tube to the water and steam mixture in the tube had a constant value of 5900 Btu/(hr) (F) (sq ft of inner surface of tube). The first two assumptions are probably tolerably accurate, but the third is subject to considerable error. It was assumed also that the heat transferred to the walls of the furnace as a whole was equal to the calculated unit rate of heat absorption multiplied by the projected area of the furnace walls. Since the walls do not have plane surfaces, this assumption, while approximate, is not exact.

In spite of all the possible errors which may have crept into the estimates of the heat absorption calculated by the ΔT -method, nevertheless the average error could not have been great because of the close agreement of the results obtained by this method and the heat-balance method.

Measurement of Saturation Temperature. It was originally assumed that the average temperature of the mixture of boiling water and steam in the tubes of all walls and at all elevations might be represented by the saturation temperature corresponding to the drum pressure. It was noted in analyzing the

results that the temperature measured by the thermocouples, peened to the backs of four rear waterwall tubes just above the hopper at elevation 463 ft did not check the temperature obtained from drum pressure readings. A review of the data indicates that the average pressure drop from the drum to the superheater outlet based on gage readings is as follows:

Evaporation (a) 1000 lb of steam per hr	Pressure drop (b), psi	(b) \times 10,000 (a) ²
625	77	1.97
460	25	1.18
330	29	2.66

From this table it is obvious that one or both pressure gages are in error. A change of 25 psi represents a change of 3.23 deg F in saturation temperature at a pressure of 950 psig. Hence a 25-psi error in pressure-gage measurement introduces in the ΔT -method an error of about 10 per cent in the calculated rate of heat absorption at full load, and of about 14 per cent at half load. With regard to the back-face thermocouple temperature measurements, differences as great as 7 F were measured between adjacent tubes in one round of measurements. Thus, while the averaging of all readings may have eliminated most of the error, some error probably still exists. After some consideration it was decided by the authors of Part I to use the thermocouple measurements to determine saturation temperature.

The assumption that saturation temperature is constant for all elevations is inexact, however, since the pressure and hence the saturation temperature is higher at the lower levels and lower at the upper levels of the furnace. Since the fluid along the length of the furnace tubes consists of saturated water and steam in varying proportions, it is necessary to know something about the circulation characteristics of the unit in order to determine the change in pressure with change in elevation. Circulation tests run in September, 1948, indicated that there was no material change in the total weight flow rate of water in the furnace tubes between half load and full load. From circulation calculations it was estimated that for all tests the saturation temperature was approximately 0.4 F higher in the hopper tubes at the lowest thermocouple elevation, and about 1.7 F lower in the roof tubes at the highest thermocouple location than in the tubes at the 463-ft elevation. The over-all correction was calculated to be plus 0.7 F.

Weighted-Average Values of ΔT . A sketch of the development of the furnace walls showing the location of thermocouples is found in Fig. 3. The dead thermocouples are underlined. The furnace is divided into several areas from A to Q, inclusive. The average ΔT for each area is the average of the ΔT -averages of the rows in the area. The sum of the products of each area by the average ΔT of the area, divided by the total area in which the thermocouples were installed, yields a weighted average ΔT . The weighted average ΔT -values thus calculated, including the $+0.7^\circ\text{F}$ correction mentioned, are tabulated in column 10 of Table 1.

As previously stated, thermocouples were not installed on the inclined rear-wall roof (K), or on the slag screen (I and J). After examination of the data it was thought reasonable to assume that, (1) the average ΔT due to radiation only in the upper screen (I) was equal to the average ΔT of roof (A); (2) the average ΔT in lower slag screen (J) due to radiation only was equal to the average ΔT of the front wall at elevation 525 ft; and (3) the average ΔT of the rear-wall roof (K) was equal to the average ΔT for the other three walls at elevation 511 ft. Applying these values of ΔT to areas (I), (J), and (K), the weighted average ΔT for each test for all furnace areas was calculated. The results, including the $+0.7^\circ\text{F}$ correction, are tabulated in column 11 of Table 1.

In column 12 of Table 1 is tabulated the difference between the final weighted average ΔT and the average ΔT taken from Part I for each test. While the differences are within the probable error of the tests and might be neglected, the weighted-

average values of ΔT should be more accurate and will be used hereafter in this paper.

HEAT-BALANCE METHOD

Some Sources of Error. Part II describes the methods of test and calculation of the heat-balance data. That paper notes that measurements of gas flow and direction were not taken and that the average gas temperature and gas composition for each test were calculated from simple numerical averages of the measurements with appropriate corrections. A possible small source of error lies in the air-leakage into the gas was equal to 5 per cent by weight of the gas entering the air heater. Probably the greatest source of error outside of the possible error in the corrections to the thermocouple measurements lies in the fact that only one traverse of the gases leaving the furnace could be made on each test. In this connection it should be noted that at full load the spread of temperature of the gas leaving the furnace was over 500 F. However, the gas composition was quite uniform, the deviation in per cent excess air rarely exceeding 10 per cent.

Weighted-Average Values of Furnace Exit-Gas Temperature. The sampling doors used for gas-temperature and gas-analysis measurements are not uniformly spaced across the boiler. For this reason simple numerical averages of the measurements where the spread is large may lead to error in the results. A method of obtaining a weighted-average furnace exit-gas temperature is shown in Fig. 4 in which isothermal lines of gas temperature for test No. 15A are drawn. Note that sampling

doors A and F are relatively close to the side walls where the gas temperatures are lower on the average than the temperatures closer to the center of the furnace.

The furnace outlet is divided into 3 vertical strips (R), (S), and (T). Center strip (S) contains temperature measurements taken through sampling doors (B), (C), (D), and (E) which are uniformly spaced. The width of strip (S) equals 4 times the uniform door spacing. Side strips (R) and (T) are equal in width. The center-line temperatures of strips (R) and (T) were determined by making an isothermal map for each test and by interpolating between the isothermals.

The sum of the average strip temperatures, each of which was multiplied by the ratio of the respective strip area to the total, yielded a weighted-average furnace exit-gas temperature. However, the calculated weighted-average temperatures vary only 5 F to 15 F from the temperatures obtained by simple arithmetic averaging in Part II. Values of furnace exit-gas temperature obtained by both methods of averaging, as well as the differences, are given in Table 2. While there are many other methods of averaging, the method just described was used, since it corrects for the lower gas temperatures measured near the walls but places a minimum of reliance on values which do not represent actual measurements.

Comparison of Furnace Exit-Gas-Temperature Data With Other Data. Inspection of furnace exit-gas-temperature data, as com-

FIG. 4 DISTRIBUTION OF TEMPERATURE, DEG F, AND DIVISION OF FURNACE GAS OUTLET INTO AREAS FOR COMPUTING WEIGHTED-AVERAGE FURNACE EXIT-GAS TEMPERATURE, TEST NO. 15A

pared to other test data, indicates that there may be relatively large errors in the values of average gas temperatures of a few

FIG. 5 COMPARISON OF SUPERHEATER HEAT DUTY AND FURNACE EXIT-GAS TEMPERATURE, DEG F, AT FULL LOAD (Number designates test.)

of the full-load tests. Several means are available to determine for which tests the temperature data appear to be the least reliable. One method of analysis is to compare gas temperature with convection-superheater duty at constant load and constant excess air. In Part I the necessary data for determining superheater duty is given except for the heat given up by the condensation of saturated steam in the inlet-superheater header to the condenser coils provided to maintain a constant final steam temperature. The rate of flow of water through the condenser coils was determined from a calibration curve of the condenser control valve. From the flow rate and the observed water-temperature rise, the heat transferred in the inlet-superheater header was estimated. Calculated superheater duty for the full-load tests is plotted against weighted-average furnace exit-gas temperature in Fig. 5.

Full-load-performance calculations were made of the rate of change of superheater duty with change in furnace exit-gas temperature at constant excess air, and of superheater duty at

constant gas temperature for three rates of excess air, namely, 17, 25, and 30 per cent. From these calculations the slope of and spacing between the lines drawn in Fig. 5 were determined. It was assumed that the 30 per cent excess-air line passes through the point for test No. 21. We may draw the tentative conclusion that values of gas temperature appear high for tests Nos. 15A and 19, and low for test No. 16.

Another method of analysis is to make plots of furnace exit-gas temperature against per cent excess air at constant secondary-air vane position, and also against secondary-air vane position at constant excess air. These plots are shown in Figs. 6 and 7 and corroborate the tentative conclusion drawn from Fig. 5 except for test No. 19. A check of ΔT and heat-balance data indicates that at 17 per cent excess air, an increase in the secondary-air vane position from 40 per cent (test No. 18) to 60 per cent (test No. 19) results in reduced heat absorption in the furnace and in a higher exit-gas temperature. It appears that the observed position of the condenser control valve for test No. 19 may have been an error.

Relationship of Furnace Exit-Gas Temperature to Furnace Heat-Absorption Rate. In predicting furnace performance, designers depend upon empirical data to calculate the rate of furnace heat absorption and the corresponding furnace exit-gas temperature. In Fig. 8 are plotted values of furnace heat-absorption rate per square foot of furnace projected area against average absolute furnace exit-gas temperature to the 4th power.

The straight line drawn in Fig. 8 represents the equation

$$Q = C \left[\left(\frac{T_a}{1000} \right)^4 - \left(\frac{T_w}{1000} \right)^4 \right]$$

where

Q = furnace heat-absorption rate, Btu/(hr) (sq ft of projected area)

C = const = 1000

T_a = average furnace exit-gas temperature, deg R

T_w = average furnace tube-wall temperature, assumed to be 1040 deg R

Note that this line passes through those points for which the secondary-air vane position was approximately 40 per cent (neglecting test No. 15A), that those points representing tests having a secondary-air vane position of 50 per cent fall below

FIG. 6 RELATION BETWEEN FURNACE EXIT-GAS TEMPERATURE, DEG F, AND EXCESS AIR FOR THREE SECONDARY-AIR VANE POSITIONS AT FULL LOAD

(First number designates test; second number designates per cent opening of secondary-air vanes.)

FIG. 7 RELATION BETWEEN FURNACE EXIT-GAS TEMPERATURE, DEG F, AND SECONDARY-AIR VANE POSITIONS FOR THREE VALUES OF EXCESS AIR AT FULL LOAD

(First number designates test; second number designates per cent excess air.)

the line, and those that represent tests having a secondary-air vane position of 60 per cent fall off even farther below the line. Fig. 8 shows that for eight-burner operation with the burner secondary-air vanes set for maximum heat-absorption efficiency (40 per cent open), the furnace heat-absorption rate is related to furnace exit-gas temperature by the foregoing equation. It follows that for the operating conditions given, if the furnace heat input and excess air at the furnace outlet are known, the heat-absorption rate and exit-gas temperature from the furnace may be calculated. For four-burner operation, particularly when the lower row of burners is fired (test No. 29) the value of C in the equation is greater, and may be as high as 1240. Where the vane position is 50 or 60 per cent open, the equation holds

toerably well at three-quarters load but at full load the value of C drops off to approximately 980 and 850, respectively.

CORRELATION OF ΔT AND HEAT-BALANCE DATA

In Fig. 9 furnace heat-absorption efficiency, calculated by the ΔT and heat-balance methods is plotted against excess air for the full-load tests. Note that the points for tests Nos. 15A and 16 are not in agreement with the other data, and also that the furnace heat-absorption efficiency, calculated by the ΔT -method for test No. 17 appears to be out of line. In Fig. 10 furnace heat-absorption efficiency, calculated by both methods, is plotted against secondary-air vane position for the full-load tests. Again, notice that the points for the tests previously mentioned are not in agreement.

It had previously been found that furnace exit-gas-temperature measurements for test Nos. 15A and 16 seemed less reliable than for the other full-load tests. It now appears that the ΔT -data for these tests are also less reliable and by a greater margin. The maximum deviation from the lines drawn in Figs. 9 and 10 is about 10 per cent for the ΔT -data (test No. 16) and

FIG. 8 RELATION BETWEEN FURNACE HEAT-ABSORPTION RATE AND FURNACE EXIT-GAS TEMPERATURE T_o , DEG R

about 3 per cent for the heat-balance data (test No. 16). These values are by no means excessive and indicate that reasonably accurate results of furnace performance may be obtained by either method of testing.

From Figs. 9 and 10 it appears:

- 1 That the furnace heat-absorption efficiency decreases as excess air is increased at constant secondary-air vane position.
- 2 That the furnace heat-absorption efficiency decreases as the secondary-air vanes are opened at constant excess air.

Statement (1) confirms past observations of the performance of radiant superheaters which give a lower steam temperature as the excess air is increased. Statement (2) applies to the adjustment of the burners used on the Paddy's Run boiler and shows

FIG. 9 RELATION BETWEEN FURNACE HEAT-ABSORPTION EFFICIENCY AND EXCESS AIR FOR THREE SECONDARY-AIR VANE POSITIONS AT FULL LOAD

FIG. 10 RELATION BETWEEN FURNACE HEAT-ABSORPTION EFFICIENCY AND SECONDARY-AIR VANE POSITION FOR THREE VALUES OF EXCESS AIR AT FULL LOAD

that by means of burner adjustment, the heat absorption in the furnace may be varied.

In Fig. 11 the values of heat absorption obtained by both methods are compared. On the whole, the data appear to be in excellent agreement as do the data in Fig. 12 in which U_o , the over-all average heat-transfer coefficient, is plotted against ΔT . If runs Nos. 15A, 16, and 17 are neglected, Fig. 12 shows that

FIG. 11 COMPARISON OF CORRECTED FURNACE HEAT ABSORPTION COMPUTED BY HEAT-BALANCE AND ΔT -METHODS (Number designates test.)

FIG. 12 CORRELATION OF CORRECTED FURNACE-WALL TUBE OVER-ALL AVERAGE HEAT-TRANSFER COEFFICIENT WITH CORRECTED VALUES OF ΔT

a fair average value of U_o for all runs would lie between 1030 and 1050 Btu/(hr) (F) (sq ft of projected area).

In Fig. 13 the furnace heat-absorption rate is plotted against the net heat available in the furnace above 80 F for the tests in which the secondary-air vanes were 40 per cent open. In Fig. 14 furnace heat-absorption efficiency is plotted against the heat available for the same tests. Only one curve is drawn in each figure showing the heat absorption at 25 per cent excess air, since only single points are available for 17 and 30 per cent excess air. It has been shown that at full load, the heat-absorption efficiencies decreased on opening the secondary-air vanes. At three-quarters load, maximum heat-absorption efficiency was obtained at a setting of 35 per cent open. At one-half load only one test was run with 8 burners and that with a vane position of 30 per cent open.

CONCLUSIONS

The following conclusions have been reached in this study.

FIG. 13 RELATION BETWEEN FURNACE HEAT ABSORPTION AND NET HEAT AVAILABLE TO FURNACE
(First number designates test; second number designates per cent opening of secondary-air vanes.)

1 With care in testing, furnace performance may be determined by either the heat-balance method or by the ΔT -method with a fair degree of accuracy.

2 The over-all average heat-transfer coefficient U_o , through the tube wall and inside tube film was 1030 to 1050 Btu/(hr) (F) (sq ft projected area). From this, the calculated film coefficient is 5500 Btu/(hr) (F) (sq ft of inside tube-wall surface).

3 For eight-burner operation with secondary-air vanes 40

FIG. 14 RELATION BETWEEN FURNACE HEAT-ABSORPTION EFFICIENCY AND NET HEAT AVAILABLE TO FURNACE
(First number designates test; second number designates per cent opening of secondary-air vanes.)

per cent open, the average furnace heat-absorption rate Q , the average furnace exit-gas temperature T_o , and the average furnace tube-face temperature T_w , are related as follows

$$Q = 1060 \left[\left(\frac{T_o}{1000} \right)^4 - \left(\frac{T_w}{1000} \right)^4 \right]$$

4 In general, the conclusions of Part I and Part II, with some slight modifications to the calculated results found in Tables 1 and 2 of this paper are valid.

ACKNOWLEDGMENT

The authors wish to express their appreciation to Mr. John Blijard for his very helpful criticisms and suggestions.

Furnace Heat Absorption in Paddy's Run Pulverized-Coal-Fired Steam Generator, Using Turbulent Burners—Discussion

THE following discussion applies to the three papers published in this issue of the Transactions as Parts I,¹ II,² and III,³ under the subject title.

OLLISON CRAIG.⁴ The tests made on the boiler at Paddy's Run Station determine heat absorption by radiation in the furnace walls by measurement of gases leaving the furnace and not by measuring the temperatures of the boiler tubes in the furnace, as was done on a test at Tidd Station. The method used at Paddy's Run no doubt gives determination of heat absorption by radiation in the furnace more accurately. With two exceptions the average of measured temperatures leaving the furnace checks reasonably close with temperatures calculated from Orrok's modified formula. One of these exceptions is test No. 29 and is accounted for by the fact that the lower burners were used at the light load. The other exception is test No. 22, and there is no apparent explanation.

The distribution of temperature as indicated in Fig. 5 explains, as pointed out in the paper,² why, in practice, slag troubles are encountered even though the average temperature of the gases is below the slagging temperature of the ash. Due to the way in which the gases approach and flow to and through the furnace exit, the temperature of the gases at the lower part of the exit are some 300 deg higher than the average gas temperatures. An explanation is given in the paper to the effect that this is because of the difference in velocity of exit at the top and bottom of the exit openings. Actually, it would seem that those gases which leave at the top of the exit opening may have been in the entire furnace for a longer period of time and on the average may have radiated heat to furnace water tubes from a shorter distance than was the case with most of the gases which entered at the bottom of the furnace exit. In addition, there has been a greater distance and a greater time interval between the point at which combustion was completed in the furnace and the top point of exit of the gases than would be the case with the bottom point of furnace exit.

Slag formation at a furnace exit can be materially different with the same amount of coal burned with the same excess air in the same furnace, depending upon the point at which combustion is completed. This is a fact well known in stoker operation and is one of the reasons for using overfire jets in stoker operation.

A knowledge of heat absorption in a furnace envelope is necessary because, (1) it is necessary to have the gases leave under such temperature conditions that slag will not be formed in the gas passes of the boiler and in the superheater region; (2) the temperature of the gases entering the superheater region must be known, in order to determine the design of the superheater. The

results of the tests at Paddy's Run are excellent from both of these viewpoints. Similar information is desirable with other methods of burning fuels and also with other fuels than coal. The results which are obtained with other methods of firing and with other fuels are surprisingly different.

F. G. ELY.⁵ The authors^{1,2,3} have made an excellent presentation of test data dealing with a subject which involves many complexities. It is encouraging to find that their correlations are comparatively good, which may in part be attributed to improved techniques of traversing and to the circumstance that ash deposits on the furnace-wall surfaces remained generally consistent on comparative tests.

For critical appraisal of the data, the authors have made use of the superheater as a calorimeter, and from its indications find justification for considering tests Nos. 15-A and 16 less reliable than the other tests.

This procedure of cross-checking results by study of the performance of component equipment seems very proper and desirable and extends the facilities of testing beyond the limitations of the ΔT -method and the heat-balance method.

In this design of unit, the furnace boundary itself comprises the major portion of the steam-generating surface, and it is possible to draw a further comparison by calculating the steam-generating duty from enthalpy of saturation, feedwater leaving economizer, and metered steam output. In Fig. 1, herewith, the test points of

FIG. 1 FURNACE ABSORPTION AS PER CENT OF TOTAL GENERATION

furnace heat absorption by the heat-balance method are plotted as percentages of total generation and are shown to range from 74 to 86 per cent, depending upon load and operating conditions.

If it be assumed that the proportioning between furnace and convection bank is a function of excess air alone, the results for tests Nos. 19 and 21 are cast in doubt, and the influence of burner vane position is minimized. If, however, the influence of the

⁴ Vice-President, Riley Stoker Corporation, Worcester, Mass. Fellow ASME.

⁵ Research Engineer, Research and Development Department, Babcock & Wilcox Company, Alliance, Ohio. Mem. ASME.

burner vanes is considered primary, some question would exist for the relationship of tests Nos. 15, 16, and 17.

Discrepancies of this order may lie in the inherent errors of temperature measurement by traverse, or in the variations caused by ash deposit on the furnace walls. On the latter point it is recommended that the S-A factors as developed by Mumford and Bice⁶ be applied to observed furnace conditions to note their effect in correlation of the test points.

It is further recommended that for future programs of furnace testing, more emphasis be placed on obtaining check or repeated tests, to give statistical weight to the averaged results, and to disclose the range of performance that may occur in day-to-day operation of the equipment.

H. F. MULLIKIN.⁷ MHVT furnace outlet-gas temperatures, as obtained by Messrs. Corey and Cohen² appear low to the writer. The temperatures of 2060 F at a furnace heat-available rate of 95,000 Btu/(sq ft)(hr) and 1730 F at a furnace heat-available rate of 50,000 Btu/(sq ft)(hr), as given in Fig. 9 of the paper, are about 190 deg F and 130 deg F below values that would be expected, according to the writer's experience.⁸ Is it possible that the special design HVT thermocouples read low during the test? Platinum thermocouples tend to lose calibration rapidly. Were they checked before and after every test? Was difficulty experienced with ash plugging toward the end of a run?

The authors are to be complimented on the completeness of the test procedure.

A. A. ORNING.⁹ The statement by the authors of Part I,¹ that it is impossible to measure flame shape, merits further consideration. The inference probably intended was that flame shape is not a readily measurable quantity, while secondary-air vane opening and burner-box pressure, factors which determine flame configuration in the furnace considered, are quantities subject to measure and control. It should not be inferred that flame shape is incapable of estimation. The objective of the furnace-performance tests, to relate furnace heat absorption and its distribution in the furnace to furnace geometry and operating variables, scarcely can be accomplished without some estimate of flame configuration as the intermediate between operating conditions and heat transfer.

Since the flame originated at the burners and followed some systematic path toward the furnace outlet, the ΔT -contours at any level should have relation to those at other levels. The prevalence of ash deposits on the back wall opposite the burners accounts for low heat transfer to that surface, although it probably was blanketed by the most intense flame within the furnace. The flame became less intense or occupied a smaller cross-sectional area at higher levels in the furnace. The gas temperatures and compositions reported in Part II² indicate two flame cores entered the furnace outlet. The ΔT -contours suggest only one radiant core except near the front wall just below the furnace outlet.

The rotation imparted at each of the eight burners was of such a sense as to create a pattern of eight eddies across the furnace. However, they probably degenerated into two eddies which best filled the rectangular cross section, and each contained a maxi-

mum of radiant intensity. Placed near the center of the furnace, the two centers of maximum intensity would not be reflected in the ΔT -contours. However, the sloping back forced the flame against the front wall so that the two maxima appeared on the front wall just below the furnace outlet. Flame sweeping near the front wall would account for the third maximum generally appearing in Figs. 22-28, inclusive, of Part I.¹ It would be interesting to know whether visual observation suggested two flame cores sweeping near the front wall at that level.

The ΔT data are missing for some points indicated on the thermocouple-location identification diagram. Had the corresponding couples completely failed? Other couples appear to be faulty. The ΔT 's reported for positions 6-14 and 7-10 are generally high under all operating conditions. What criteria were used to determine that a given couple was faulty?

L. B. SCHUELER.¹⁰ The three papers^{1,2,3} presenting the test data and analytical report on the Paddy's Run boiler offer another set of complete information of interest and use to the boiler-furnace designer and user. The data appear to be well taken and have benefited from some improvement in instrumentation and technique since the Tidd boiler tests of several years ago. Favorable furnace-outlet location and profile, together with improved instrumentation, indicate that the gas-temperature and composition data should be most reliable.

A study of the furnace tube ΔT isotherms in Part I¹ indicates that the rather compact bunching of all burners in one wall is not conducive to uniform and effective heat transfer to the furnace walls. The front, or burner wall, shows only moderate absorption rates probably because the flame is traveling away from the wall, and the wall is partially screened by the cold layer of coal and air leaving the burners. The side walls show fairly good absorption rates, due to greater exposure to active flame, and a beneficial sweeping action of the flame without much slag deposition. However, these walls have less area than the front and rear so that their effect is thereby minimized. The rear wall, which should benefit most by virtue of its position opposite the burners, suffers somewhat from slag deposition by flame impact in the middle zone, although the hopper slope performs remarkably well. The upper portion of the entire furnace appears to suffer from lack of proximity and direct exposure to active flame.

All in all, it would appear that burner position, furnace shape, or both could well be changed to achieve more effective heat absorption throughout much of the furnace. The physical and operating convenience of grouping all burners in one wall at the main operating level must be weighed against the evident unfavorable flame pattern produced in a conventional furnace.

The uniformity of gas composition at the furnace outlet, as brought out in Part II,² is testimony of good coal and air distribution and combustion. The indicated effects of changing burner vane positions are interesting but not as pronounced as might be hoped for. It is possible that the extremely high pulverized-coal fineness for all tests acts to minimize the effects of vane position, and it would be interesting to determine whether the effects are greater with coal of normal fineness, say, 70 per cent through 200 mesh. Correspondingly, the present tests show virtually no carbon loss whereas vane manipulation with lower fineness and lower volatile fuels might encounter high carbon losses as a consequence.

CLOSURE BY R. I. WHEATER AND M. H. HOWARD

We agree with Mr. Ely that it would be advisable to verify the furnace-performance characteristics by incorporating additional check tests in future programs of this nature. Considera-

⁹ Coal Research Laboratory, Carnegie Institute of Technology, Pittsburgh, Pa. Mem. ASME.

tion should be given to reducing the duration of each test, which would permit running more check tests and reduce the volume of data to be analyzed. This would also hold operating variables to a minimum.

Dr. Orning is correct in emphasizing that it is not impossible to measure flame shape. However, due to the difficulties involved in accurately measuring flame shape and duplicating it under various test conditions, burner settings, which could be duplicated and do control flame shape, were used as a reference.

The relation of the ΔT contours at various levels is not only affected by the ash accumulations on the rear wall but it is also affected by eddies in the flow path and by shielding of the emitting body. While some of the ΔT contours indicate two radiant cores existing in the upper part of the furnace, they were not visible through the available doors and no flames existed at this elevation.

On several occasions prior to the tests, the thermocouples were checked as the unit was taken off the line to assure that they indicated saturation temperature, as the pressure was reduced without fire in the furnace. The thermocouple at the location omitted from the ΔT data had either failed or consistently recorded a temperature considerably below saturation temperature.

Mr. Schueler has presented an excellent analysis of the distribution of heat absorption by the walls and its relation to the burner locations. The location of the burners and the furnace shape both affect the distribution of heat absorption by the walls but additional data is required to determine the optimum firing arrangement. Available data has however indicated that maximum furnace efficiency is obtained when the fires are located as near as possible to the bottom of the furnace.

Comparison of these results with additional heat absorption distribution data as it becomes available should enable the designer to locate the burners and shape the furnace to obtain the optimum heat-absorption distribution throughout much of the furnace.

CLOSURE BY R. C. COREY AND PAUL COHEN

Mr. Craig's explanation for the vertical temperature gradient at the furnace outlet agrees with that proposed by the authors. The gas-residence time of the stream lines leaving the top of the furnace outlet is believed to be longer, and therefore the linear velocity lower, than those leaving the lower portion of the outlet. Also considered as a possible factor was the heavier ash deposits on the rear than on the front wall, causing less net heat transfer from the gases along the rear wall. He calls attention to the need for similar investigations of furnaces fired by other methods. The Committee recognizes that all types of firing must be investigated if fundamental furnace heat-transfer relations are to be discovered. To the present time, however, it has been expedient to concentrate upon pulverized-coal-fired units, but during 1950 it is expected that a series of tests with a spreader-fired unit will be completed.

Mr. Ely makes an interesting comparison between the operating variables, excess air and vane opening, and the furnace heat absorption as per cent of total steam generation.

The question raised is whether tests 19 and 21, or tests 15A, 16, and 17 are in error, depending upon whether the relative heat-absorption efficiency of the furnace is affected by the excess air alone, or is influenced primarily by the vane opening. However, it will be noted from the three-variable plot, Fig. 11 of Part II, that each of the variables influences furnace heat absorption, the effect being greatest at full load. If it is assumed as a rough approximation that excess air and vane opening have the same relative effect in the ranges that were studied, then Mr. Ely's plot indicates test No. 15A to be somewhat low and No. 16 to be somewhat high. But it is not known definitely whether the deviations

were due to instrumental errors or to unusual ash patterns on the furnace walls for these two tests.

The authors agree with Mr. Ely that check runs should be made as often as possible in these furnace investigations. However, because of the number of independent variables that must be considered in the limited time available for such tests, it has not been possible to make as many duplicate tests as desired.

Mr. Mulliken suggests that the furnace-outlet temperatures seem low for heat-release rates of 95,000 and 50,000 Btu/(sq ft) (hr). Rigorous tests, in which direct comparisons were made in the furnace between B&W MHVT and the modified shields, showed the latter to be approximately 50 F lower. The test results were corrected accordingly and used for the enthalpy calculations. In addition, to detect possible contamination of the junctions, the test couples were calibrated frequently against a standard couple in a special electric furnace, and defective junctions were renewed.

Plugging of the shields always is a problem, particularly at full load and low excess air. However, the aspirating system was arranged so that the pressure drop across the shield was known at all times, and when it became too high the shield was replaced. Generally, the temperature at a given location in the furnace outlet was found to be the same with the new shield as with the one that was replaced, suggesting that inaccuracies due to reduction of cross section of the shield by ash were negligible. It was interesting to find that the emf of couples fitted with type E or G shields did not change noticeably, at constant mass flow of gas, even when as much as 90 per cent of the free area of the shield became plugged with ash.

Mr. Schueler's suggestion that the effect of vane setting might be more pronounced with coarser coal is probably correct. That is, for a given coal and excess air, the rate of change of flame surface with respect to vane opening may increase as the coal fineness decreases. Of course a relation of this kind would apply only within the limits of stable ignition.

CLOSURE BY H. H. HEMENWAY AND R. I. WHEATER

Mr. Craig observes that the averages of the measured temperatures leaving the furnace check reasonably with temperatures calculated from Orrok's modified formula except for test Nos. 29 and 22. General equations such as Orrok's for calculating furnace performance deal only with those few factors having the greatest influence on furnace heat absorption and are usually fairly accurate. One factor not normally considered is flame shape on which subject Mr. Orning has some very interesting comments. On the Paddy's Run unit, flame shape was varied by changing the

FIG. 2

position of the burner secondary-air vanes to alter the whirl imparted to the air before it entered the furnace. By opening these vanes this whirl was reduced which increased the length and reduced the spread of the flame causing a lowering of furnace heat absorption. This reduction of heat absorption on test No. 22, run with 60 per cent vane opening, probably caused the results to deviate from the results calculated by the Orrok equation.

Mr. Ely's plot of furnace absorption as per cent of total generation provides an excellent means of cross checking results. If the point for test No. 15A (B) is raised and the point for test No. 16 (C) lowered as suggested in Part III, the resulting plot will show rather well the effects of excess air and per cent vane opening on furnace heat absorption.

The authors may have been remiss in omitting the use of the S-A factors developed by Mumford & Bice⁶ and recommended by Mr. Ely but the ash deposits on the furnace-wall surfaces were so minor in nature and varied so little between tests that early ex-

amination of the data indicated little change in the correlation of the test points.

Mr. Schueler expresses the opinion that the furnace-wall surfaces might be more effectively used by making changes in burner grouping, furnace shape, or both. The relatively poor results obtained on tests with the secondary air vanes open greater than 40 per cent may have led to this observation. At Paddy's Run the vane settings were varied to study the effect of this particular factor on furnace performance. Normally the air vanes are set at the position giving optimum performance. In this case the setting is 40 per cent open. As a matter of interest a comparison was made of the results of the tests on the Tidd tangentially fired furnace when the burners are horizontal, and the Paddy's Run furnace with burner air vanes 40 per cent open, both at approximately 25 per cent excess air. This comparison is shown in Fig. 2. Note the closeness of the results obtained by the two different methods of firing.

The Evaluation of Steam-Power-Plant Losses by Means of the Entropy-Balance Diagram

By ALLEN KELLER,¹ LYNN, MASS.

This paper deals with a method of isolating and evaluating the various cycle losses of a condensing steam power plant. Each loss in the steam cycle causes an increase of entropy. By considering each of these entropy increases on a "per hour" basis instead of a "per pound" basis, the heat rejection to the condenser caused by each individual loss can be evaluated quickly.

NOMENCLATURE

The following nomenclature is used in the paper:

G = mass flow, lb per hr
 H = enthalpy flow, 1000 Btu per hr
 P = pressure, psia
 q = sensible-heat flow, Btu per hr
 Q = sensible heat, Btu
 s = specific entropy, Btu/deg F/lb
 S = entropy flow, Btu/deg F/hr
 S' = entropy, Btu/deg F
 t = ordinary temperature, deg F
 T = absolute temperature, deg F
 v = specific volume, cu ft per lb

INTRODUCTION

The concept of a flow of entropy can, at times, be used advantageously to evaluate the different losses in a condensing steam power plant and to get quick answers as to the over-all effect of design changes. An entropy-balance diagram can do this, because entropy is a measure of the unavailability of energy from the standpoint of a complete power plant consisting of boiler, turbine, condenser, feedwater heaters, pumps, and so forth.

DEFINITION OF AN ENTROPY-BALANCE DIAGRAM

When sensible heat is added to a quantity of matter, the change of entropy is given by the equation

$$dS' = \frac{dQ}{T} \dots \dots \dots [1]$$

Conventional steam tables assume that the entropy of saturated water at 32 F is zero. For water at temperatures above 32 F and for steam, the entropy is greater than zero because the sensible-heat content is greater than that for saturated water at 32 F. For steam, water, or ice at any condition, the entropy may be obtained by making a proper integration of Equation [1] from saturated water at 32 F to steam, water, or ice at the condition specified.

Equation [1] makes no mention of the quantity of matter to which heat is added because, as a differential-equation, it may be

¹ Assistant Division Engineer, Turbine Engineering Division, General Electric Company. Mem. ASME.

integrated to determine the entropy of any quantity of matter. Conventional steam tables give the result of this integration for 1 lb (mass) of water. Thus the steam table lists values of "specific entropy" or entropy per pound of fluid.

If entropy per pound of fluid be multiplied by the fluid-mass flow, in pounds per hour, the product is the entropy flow per hour. An entropy-balance diagram is, then, a chart similar to a heat-balance diagram on which is represented the rate of flow of entropy throughout the entire steam cycle of a power plant. There is, however, one important difference between a heat-balance diagram and an entropy-balance diagram. On the heat-balance diagram, the boiler, turbine, feedwater pumps, and condenser are the only places where heat (or more properly enthalpy) is added to or subtracted from the thermodynamic medium itself. At all other points in the cycle, enthalpy is only transferred, as from steam to water in a feedwater heater. On the other hand, on an entropy-balance diagram the total entropy of the thermodynamic fluid is increased whenever a cycle loss takes place. For example, consider an extraction steam pipe leading from the turbine to a feedwater heater. The pressure drop in this pipe will cause an increase in the entropy of the steam flowing in the pipe, and the hourly entropy increase taking place within the pipe will be a direct measure of the cycle output loss caused by the pipe fluid friction.

CONSTRUCTION OF AN ENTROPY-BALANCE DIAGRAM

Fig. 1 is a conventional heat-balance diagram for a typical steam-turbine power plant having an 11,500-kw AIEE-ASME preferred standard turbine-generator set operating at rated load. On this diagram, the heat-radiation loss is assumed to be zero, and the power required to drive the hot-well pump and boiler feed pump is neglected. (If desired, feedwater-pumping power can be taken into account without affecting the validity of the entropy balance as a means of evaluating losses.)

The derivation of Fig. 1 is not described in this paper.

Fig. 2 is the entropy-balance diagram corresponding to Fig. 1. It is based upon the flows given on the heat-balance diagram. At each point on the diagram, the mass flow is multiplied by the specific entropy to get the entropy flow. Whenever the total entropy leaving a given piece of apparatus is greater than the total entropy entering the same apparatus, the difference between the two entropy flows is the entropy increase caused by the cycle loss taking place in the apparatus. For example, consider the steam-extraction pipe from the turbine to the No. 2 feedwater heater. The entropy flow at the pipe discharge is 9319.1 Btu/deg F/hr. This value was calculated by multiplying 5338 lb per hr flow by 1.7458 Btu/deg F/lb specific entropy.² At the pipe inlet the entropy flow is 5338 lb per hr \times 1.7344 Btu/deg F/lb or 9258.2 Btu/deg F/hr. Therefore the 10 per cent pressure drop in this pipe causes an entropy increase of 69.9 Btu/deg F/hr.

Fig. 2 shows that 143,479.2 Btu/deg F/hr is the entropy

² All properties of steam used in this paper were read from "Thermodynamic Properties of Steam," by J. H. Keenan and F. G. Keyes, John Wiley and Sons, New York, N. Y., 1936 edition.

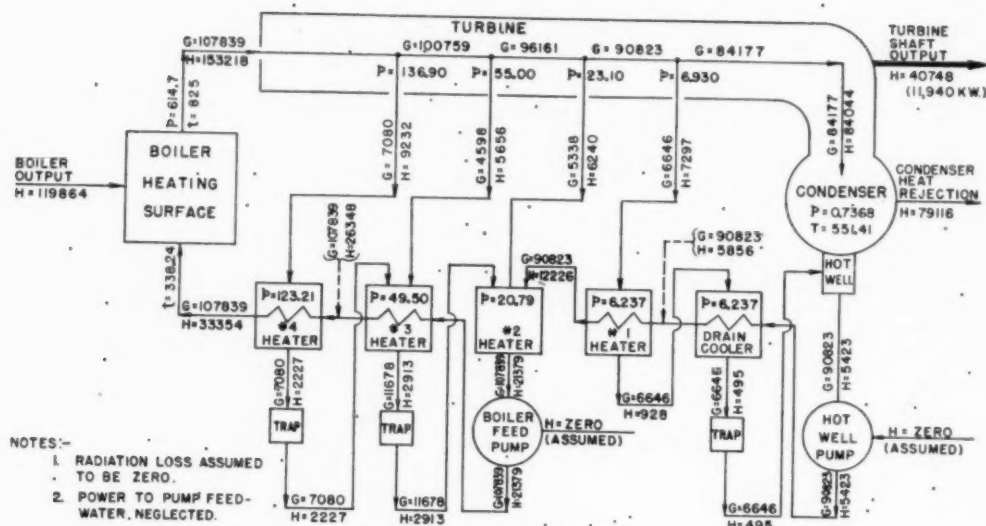

FIG. 1 TYPICAL HEAT-BALANCE DIAGRAM

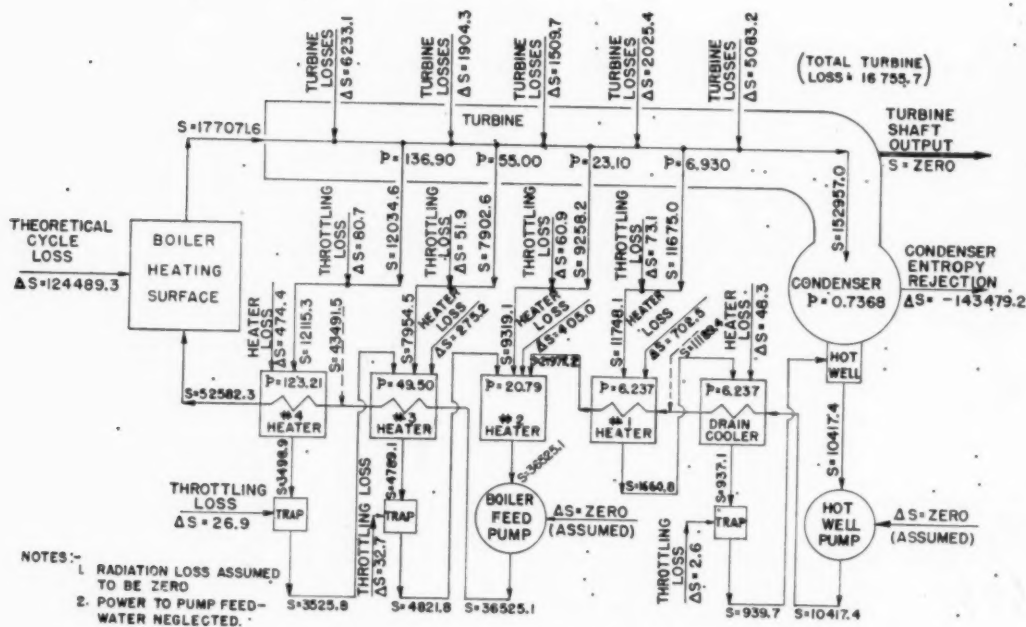

FIG. 2 TYPICAL ENTROPY-BALANCE DIAGRAM

rejection³ to the condenser circulating water. This value represents the sum of all entropy increases (ΔS) in Fig. 2. The largest single entropy increase is the 124,489.3 Btu/deg F/hr added by the boiler. This quantity represents the theoretical cycle losses for the particular flow, boiler-inlet feedwater condition, and superheated steam-outlet condition shown in Fig. 1.

³ In this paper, all values have been computed on an electrical computing machine merely to reduce the round-off errors and insure essentially perfect totals for all summations. For ordinary work such refinements usually will not be necessary.

EVALUATION OF LOSSES

Substantially all condensing power plants operate with wet steam exhausts. For such plants, the turbine-exhaust-steam temperature is a function of the exhaust pressure only. Thus when Equation [1] is applied to the heat-transfer phenomenon in the condenser, the temperature T is a constant.

Figs. 1 and 2 are based upon 1 1/2 in. Hg abs exhaust pressure. At this pressure the saturation temperature of steam is 91.72 F or 551.41 F abs ($T = t + 459.69$).

Kw los

Colum
the tur
each lo
The v

With constant temperature, Equation [1] may be written in the form

$$\Delta q = T \Delta S \dots \dots \dots [1a]$$

Thus the condenser heat rejection corresponding to the 143,479.2 Btu/deg F/hr condenser entropy rejection in Fig. 2 must be

$$\Delta q = 551.41 \times 143,479.2 = 79,115,866 \text{ Btu per hr}$$

This value agrees with the condenser heat rejection calculated by heat-balance methods as shown in Fig. 1.

To illustrate the method of evaluating individual losses, consider again the steam-extraction pipe to the No. 2 heater. A previous calculation has shown the entropy increase in this pipe to be 60.9 Btu/deg F/hr. This entropy increase must be rejected at the condenser at 551.41 F abs temperature. The corresponding heat rejection at the condenser is

$$\Delta q = 551.41 \times 60.9 = 33,581 \text{ Btu per hr}$$

This is the heat equivalent of 9.85 kw. Thus the 10 per cent pressure drop from the turbine shell to the No. 2 feedwater heater is causing a power output loss of 9.85 kw or 0.0825 per cent of the 11,940-kw turbine shaft output.

TABULATION OF ALL LOSSES FOR FIGS. 1 AND 2 POWER PLANT

Table 1 isolates and evaluates each loss in the Fig. 1 heat-balance diagram, and Fig. 2 entropy-balance diagram. This table is an illustration of the type of over-all picture of power-plant losses which may be prepared relatively quickly by means of the entropy-balance diagram.

Table 1 shows the losses associated with feedwater heating while many readers are accustomed to think of gains from feedwater heating. This difference is only a matter of viewpoint. Feedwater heating results in an efficiency gain relative to the Rankine cycle without feedwater heating. On the other hand, an actual feedwater-heating installation always results in a loss relative to the perfect regenerative feedwater-heating cycle. This latter is the viewpoint in this paper.

The derivation of Table 1 needs some explanation.

For each individual loss, column B of Table 2 lists the entropy increase as shown in Fig. 2. The total of all entropy increases is the entropy rejection to the condenser, which agrees with the value shown in Fig. 2.

The two asterisked entries require special explanation. The turbine-shaft power output of 11,940 kw has a heat equivalent of 40,748,235 Btu per hr. At 551.41 F abs temperature, this amount of heat flow is equivalent to 73,898.3 Btu/deg F/hr. This number has been included in Table 1 as the first asterisked quantity.

The 217,377.5 Btu/deg F/hr entropy increase shown as the boiler output in Table 1 was calculated as follows: Fig. 1 shows a boiler output of 119,864,000 Btu per hr. At 551.41 F abs temperature, this amount of heat flow is equivalent to 217,377.5 Btu/deg F/hr. This quantity represents the entropy equivalent at condenser temperature of the boiler heat output.

Column C shows the power output loss corresponding to each entropy increase. These were calculated by the formula

$$\text{Kw loss} = \left(\begin{array}{c} \text{Hourly} \\ \text{entropy} \\ \text{increase} \\ \text{Btu/deg F/hr} \end{array} \right) \times \left(\begin{array}{c} \text{temperature at} \\ \text{condenser, deg F abs} \end{array} \right) \dots [2]$$

Column D shows the percentage ratio of each individual loss to the turbine output and column E shows the percentage ratio of each loss to the boiler output.

The values in column C may be used to "capitalize" each of

the individual losses. Again, using the No. 2 heater steam-extraction pipe as an example, if 1 kw of extra power output at constant input is worth, say, \$100, then a capital expenditure of \$980 would be justified to eliminate completely the pressure drop in this pipe, or a capital expenditure of about \$500 to decrease the pressure drop from 10 to 5 per cent.

FEEDWATER-HEATING-CYCLE LOSSES

Fig. 3 shows the cumulative loss in the feedwater-heating cycle as a function of the feedwater temperature. This shows that a perfect feedwater-heating system would improve the overall plant efficiency (at constant boiler efficiency) by about 6 per cent.

It is difficult, if not impossible, to extract superheated steam

Fig. 3 CUMULATIVE LOSS IN FEEDWATER-HEATING SYSTEM

for feedwater-heating purposes without taking a loss relative to the extraction of wet steam. This results from the fact that the feedwater temperature leaving a heater usually is determined by the pressure of the extracted steam without regard to its superheat. Even when a feedwater heater is designed to use the superheat in extracted steam to decrease the heater terminal-temperature difference, the temperature of the feedwater leaving the heater is many degrees below the temperature of the extracted steam.

Fig. 3 indicates the portion of the loss in the feedwater-heating cycle that is caused by superheat in the extracted steam. This loss was evaluated by calculating the extra "entropy of superheat" that would have been extracted if the heat of superheat were available at saturation temperature. Fig. 3 shows that the loss from this source amounts to about 0.2 per cent at the 338 F feedwater temperature leaving the No. 4 heater.

To get an over-all idea of the feedwater-heating loss, the Fig. 3 curves cover the entire feedwater-temperature range from hot well to boiler saturation. To calculate the point at the 489 F boiler saturation temperature, a fictitious fifth stage of feedwater heating was assumed which delivers saturated water to the boiler at 614.7 psia pressure, heated by steam extracted from the turbine throttle. For this imaginary condition, the boiler heat output was kept unchanged from the actual 119,864,127 Btu per hr value by assuming a boiler mass flow of 126,685 lb per hr which is converted by the boiler from saturated water at 614.7 psia pressure to superheated steam at 614.7 psia pressure, 825 F temperature. Of this 126,685 lb per hr boiler flow, 18,846 lb per hr is then extracted from the turbine throttle to the imaginary heater, leaving 107,839 lb per hr to flow to the turbine first stage, the same as before. With this imaginary feedwater heater in the picture, the entire feedwater-heating system from hot well to boiler saturation temperature extracts 4244.5 Btu/deg F/hr less entropy from the turbine than it adds to the feedwater. This 4244.5 Btu/deg F/hr value represents the saving which could be made, if a perfect feedwater-heating system were available which delivered saturated water to the boiler.

REHEAT EFFECTS

The entropy-balance diagram is strictly correct for showing where cycle losses actually take place; however, it gives slightly conservative values when used to evaluate the gains which would be made if losses were eliminated or reduced.

Again, as an example, consider the No. 2 heater extraction pipe. Suppose that the pressure drop in this pipe were reduced and at the same time the extraction point in the turbine moved downstage slightly so as to maintain the same heater pressure. The state line enthalpy of the extracted steam would then be reduced slightly so that more extraction steam flow would be required to get the necessary heat for the feedwater heater. This increased extraction flow necessarily would cause less mass flow through the turbine low-pressure stages and hence less entropy flow to the condenser.

In evaluating the increased output that would result if the No. 2 heater extraction-pipe pressure drop were eliminated, it has been assumed that the decrease of entropy flow to the turbine exhaust would exactly equal the entropy increase in the extraction pipe. This is true except for one thing, namely, turbine stages are not 100 per cent efficient, and any reduction in the flow through a stage will also reduce the stage loss. Thus the entropy flow to condenser will always be decreased slightly more than any increase in the amount of entropy extracted.

At the turbine flange extracting to the No. 2 heater, the specific entropy is 1.7344 Btu/deg F/lb. At the turbine exhaust it is 1.8171 Btu/deg F/lb. Thus the "reheat factor" that must be

applied to entropy extraction at the No. 2 heater opening is approximately 1.8171/1.7344 or 1.048. The word "approximately" is used in the foregoing expression because an entropy of liquid must be subtracted from both numbers, which will make the true reheat factor more complicated than the simple quotient shown.

If a turbine were 100 per cent efficient relative to the Rankine cycle and had an isentropic expansion line, all reheat factors would be 1.00. Since all large turbines have Rankine-cycle efficiencies between 80 and 90 per cent, the reheat factors can never get appreciably above 1.00. About 1.10 to 1.15 is the highest reheat factor that will be encountered in any normal installation; thus considering it as unity will cause no great error in perspective for a given study.

SIMPLIFIED CALCULATION METHODS

It can be shown that for a throttling process

$$ds = -0.1850 \frac{pv}{T} d \log_e p \quad [3]$$

Since the value of pv/T generally changes very little along a turbine-expansion line, it may be considered as approximately a constant.

Using 0.585 as an approximate value of pv/T , Equation [3] becomes

$$\Delta s = +0.108 \log_e \frac{p_1}{p_2} \quad [3a]$$

in which p_1/p_2 is the pressure ratio of a throttling process, and p_1 is the higher pressure.

Table 2 shows the actual increase of specific entropy associated with the 10 per cent pressure drop in each of the four extraction pipes of Figs. 1 and 2, together with the values calculated by Equation [3a]. Table 2 shows that Equation [3a] is quite accurate as a means of estimating entropy increases caused by throttling.

Simple procedures also can be worked up for estimating quickly the entropy increases associated with heater terminal-temperature differences, and the like, without reference to a steam table.

CONCLUSIONS

The entropy-balance method is a fundamentally sound and easily applied method of isolating and evaluating the different losses in the steam cycle of a condensing power plant. Although a sizable amount of calculation work is required to make a complete analysis of a given installation; any one question may be answered quite quickly after a heat balance is available. Preliminary estimates of many losses also may be made prior to a heat-balance calculation by making judicious assumptions as to the mass flows involved.

The entropy-balance diagram is not a substitute for other methods of analysis. It is another way of looking at a problem which should be used when it is helpful and not used when other methods seem more straightforward to apply.

Discussion

R. E. HANSEN.⁴ The evaluation of cycle losses by calculation of entropy generation is convenient, particularly when losses under study are too small to show up in a heat-balance computation.

The author states on the second page of the paper that the entropy rejection (a better word than "loss") of the theoretical

⁴ Engineer, Elliott Company, Jeannette, Pa. Mem. ASME.

cycle is equal to the entropy received in the boiler. He does not define his theoretical cycle, but if the intention is to use as a reference the cycle defined by Selvey and Knowlton,⁵ the theoretical heat rejection would be increased by an amount given in the writer's paper⁶ of 1945.

It is not clear to the writer why, in Table 1, a fictitious entropy quantity representing turbine output is added to total entropy rejection in the cycle. This total does not appear to provide any additional information. Thermal efficiency of the turbine cycle may be found by dividing kw output by boiler output in kw, i.e., 11940/35122, or 34.0 per cent. Plant efficiency would be found by deducting auxiliary power before making this division, then multiplying the quotient by boiler efficiency.

The question of radiation loss is side-stepped by the assumption of zero. However, radiation can be handled quite readily in this type of computation. It may be of value to consider two types of entropy change, one by transfer, the other by generation. Entropy is increased by transfer in the boiler, and decreased by the same means wherever radiation or conduction losses occur. Entropy generation, as by pressure drop or internal heat transfer with a temperature difference, always results in an increase. Heat rate of the cycle becomes

$$\frac{3412.75 \Delta H_B}{\Delta H_B - (\Sigma T \Delta S)_r - (T \Delta S)_c} \dots \dots \dots [4]$$

where ΔH_B is the heat received in the boiler, $(\Sigma T \Delta S)_r$ is the summation of all entropy losses through radiation or conduction, multiplied by the temperature at which the loss occurs, and $(T \Delta S)_c$ is the entropy rejection in condenser multiplied by condensing temperature. Where radiation and pressure drop occur simultaneously, the entropy rejection due to radiation must be computed separately from the entropy generation due to pressure drop, in order to evaluate $(\Sigma T \Delta S)_r$; the net change affects $(T \Delta S)_c$.

The author's evaluation of the effect of an individual loss is substantially correct in so far as capacity value is concerned, unless capacity limitation lies in the generator. There is an additional value, however, due to fuel savings. For example, with a load factor such that 6000 kwhr can be generated annually from each kw of capacity, and where energy cost due to fuel averages 1 mill per kwhr the fuel saving amounts to \$60 annually. Assuming 12 per cent fixed charges, capitalized value of the saving becomes \$500 per kw, or \$4900 in the example cited by the author. This value is obtained regardless of capacity limitation, as fuel input may be reduced at the burner. Both values must of course be corrected to a plant value, by considering the effect of boiler efficiency and auxiliary loss, which increases the value of the savings.

⁵ "Theoretical Regenerative-Steam-Cycle Heat Rates," by A. M. Selvey and P. H. Knowlton, Trans. ASME, vol. 66, 1944, pp. 489-512.

⁶ "Irreversibility in the Theoretical Regenerative Steam Cycle," by R. E. Hansen, Trans. ASME, vol. 67, 1945, pp. 557-560.

Whenever entropy is discussed, the question arises as to what it is and why it is useful. Most forms of energy represent the product of a potential, such as force or voltage, by a quantity, such as distance or current. In the case of heat, temperature is the potential, but there is no readily perceived quantity by which to multiply it. This difficulty is solved by inferring the existence of entropy, and computing its value mathematically. There is no need to know any more than this about its nature, and no probability that we ever will.

AUTHOR'S CLOSURE

The comments of R. E. Hansen are all quite pertinent.

The theoretical cycle the author used as a reference on page 950 is the completely reversible regenerative cycle in which the feedwater is heated by extracting heat from the turbine at the same temperature as the feedwater. This could be accomplished, theoretically, by flowing the feedwater, in a counterflow direction, through a water jacket around the turbine shell and heating the feedwater by transferring heat at constant temperature through the turbine shell. The losses relative to the foregoing cycle caused by extracting superheated steam, as discussed on page 951 of the author's paper, are the same as those discussed in the R. E. Hansen paper,⁶ except that they are evaluated for an actual cycle with a finite number of feedwater heaters and a less than 100 per cent efficient turbine.

In Table 1 the fictitious entropy quantity representing turbine output was inserted for checking purposes only. The text on page 950 explains how the 217,377.5-Btu/F/hr entropy increase assigned to the boiler was calculated. By calculating a similar entropy flow value which, at condenser temperature, would be equivalent to the turbine power output, a check was established that turbine-power output plus turbine, condenser, and feedwater-heating-system losses equaled the boiler output, as expressed in entropy units.

Radiation as well as many other considerations were side-stepped to keep the paper short. For example, the entropy balance concept can be used to evaluate boiler feed-pump losses, which was also side-stepped by stating that boiler feed-pump power had been neglected. The purpose of the paper is to present a concept for isolating and evaluating different kinds of losses to which each engineer can fill in the necessary detail to adapt the concept to his own needs.

Much has already been written on the subject of steam-power-plant efficiencies and heat balances. Mr. J. K. Salisbury has given much thought to this subject, and his 1949 ASME paper⁷ presents another approach to the problem of evaluating power-plant losses. The entropy balance concept is just another tool which a power-plant designer may use in his work.

⁷ "Power-Plant Cycle Evaluation," by J. K. Salisbury, Trans. ASME, vol. 71, 1949, pp. 593-604.

The Gas-to-Gas Heat Exchanger as Applied to an Oxygen Plant

Plate and Interrupted Strip-Fin Design

By CLYDE SIMPELAAR¹ AND DAVID ARONSON²

The construction and performance of high-efficiency (95 per cent) counterflow heat exchangers is reported. These exchangers are of the finned-plate type employing interrupted strip fins. Comparison is made between test-core results and performance of large-size units installed in a tonnage gaseous-oxygen plant. Heat-transfer results were in good agreement but measured pressure drops on the large-size units were considerably higher than predicted from test-core results, possibly due to losses at end connections. Successful development of the true counterflow gas-to-gas exchanger adds flexibility to the design of low-pressure gas cycles as in oxygen plants, permitting the substitution of heat exchangers for regenerators.

NOMENCLATURE

The following nomenclature is used in the paper:

- a/s = ratio of total heat-transfer surface to minimum cross-sectional area per unit of length
 A = total heat-transfer and/or friction area, sq ft ($A = A_f + A_e$). This definition of area differs from Norris and Spofford (1)³ A , which is the sum of half the direct surface plus the full indirect surface)
 A_e = minimum cross-sectional area for flow, sq ft
 A_f = surface area of fins, sq ft
 A_w = surface area of direct surface, sq ft
 b = width of strip fin (distance from leading edge to trailing edge in direction of air flow), ft
 c_p = gas unit heat capacity, Btu/(lb)(deg F)
 D_e = equivalent passage diameter, $D_e = 4r_H = 4A_e/(A/L)$, ft
 f = Fanning friction factor (see dimensionless groupings)
 G = core air-mass velocity, (lb)/(hr)(ft² of A_e)
 g = conversion factor, $g = \frac{32.2 \text{ (ft) (lb-matter)}}{(\text{sec}) (\text{sec}) (\text{lb-force})}$
 (for time in hours, $g = 4.17 \times 10^3$)
 h = surface heat-transfer coefficient referred to fin average surface temperature, not to temperature at base of fin, Btu/(hr)(ft²)(deg F). Note that for conditions of test, distinction between surface temperature and base of fin is unimportant

- j = heat-transfer factor (see dimensionless groupings)
 k = thermal conductivity of gas, Btu/(hr)(ft²)(deg F/ft)
 k_s = thermal conductivity of fin material, Btu/(hr)(ft²)(deg F/ft)
 L = length of flow passage, ft
 m = $(2h/k\delta)^{0.4}$, 1/ft
 P = gas pressure, psia
 ΔP = pressure drop, lb/in.² or lb/ft²
 t = temperature, deg F
 T = temperature, deg R
 δt = temperature change of gas from inlet to outlet, deg F
 Δt_m = temperature difference between gas and metal surface, deg F
 U = over-all heat-transfer coefficient, gas₁ to gas₂ based on total area, A
 W = mass-flow rate, lb per sec or lb per hr
 x_f = effective fin length, ft
 δ, Δ = prefixes denoting difference
 δ = thickness of fin, ft
 η = fin efficiency, dimensionless
 $\eta = (\tanh x_f m)/x_f m$, approximate⁴
 μ = viscosity, lb/(hr ft)
 ρ = gas density, lb per cu ft
 ψ = fin perimeter, ft, $\psi = 2(b + \delta)$

Dimensionless Groupings

- $St = (h/Gc_p)$, Stanton's number, a heat-transfer modulus
 $Pr = (c_p \mu/k)$, Prandtl's number, a fluid-property modulus evaluated for arithmetic-mean bulk fluid temperature
 $j = (St)(Pr)^{1/3}$ = generalized heat-transfer grouping (this factor, j versus Re , defines heat-transfer characteristic of surface)
 $Re = (D_e G/\mu)$, Reynolds number, a flow-property modulus characterizing "turbulence"
 $R\psi = (\psi G/\mu)$ modified Reynolds number based on fin perimeter
 $f = \frac{\Delta P}{G^2} \frac{2g\rho}{(A/A_e)} = \text{Fanning friction factor (the } f\text{—Replot defines friction characteristic of surface)}$
 $NTU = \delta t/\Delta t$ = number of core "heat-transfer units," a dimensionless expression of "heat-transfer size" of core;
 $NTU = (\eta)(Ah/Wc_p) = (\eta)(h/Gc_p)(A/A_e)$

Subscripts

- c refers to cooler fluid, i.e., one being heated
 h refers to warmer fluid, i.e., one being cooled

³ Numbers in parentheses refer to the Bibliography at the end of the paper.

Contributed by the Heat Transfer and Gas Turbine Power Divisions and presented at the Annual Meeting, New York, N. Y., November 27–December 2, 1949, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 49—A-153.

⁴ Within the accuracy of the data it is considered justifiable to apply the fin efficiency to the entire surface. The indirect surface constitutes 85 per cent of the total surface so the uncertainty of the relative effectiveness of direct and indirect surface can have only a small effect on over-all performance.

INTRODUCTION

This new type of heat-exchanger surface for gas-to-gas service is a development of the company of one of the authors.¹ The application to commercial-size heat exchangers was carried through in co-operation with the company of the second author,² for use in its oxygen pilot plant. The importance of proper heat-exchange design in the satisfactory functioning of the oxygen plant is indicated in a separate report (2) on the performance of this pilot plant.

A broad review of oxygen technology, including a consideration of heat-exchanger requirements, was featured in an AIChE symposium in December, 1946, and was later reported (3). The newer designs of oxygen plants involve heat transfer to gases at comparatively low density and require exchangers of very high efficiency. For such service as well as other applications involving gases at low density some form of extended surface is indicated from the standpoint of economy in cost, size, and weight. Tests of several types of extended surface are reported by Norris and Spofford (1), by London and Ferguson (4, 5) and by Trumpler and Dodge (3). These were all built in comparatively small size.

The present paper describes commercial-size units built around a fin pattern corresponding to sample No. 10 of the Norris and Spofford paper (1) and core J of the London and Ferguson paper (4). The core structure which is illustrative of the flat plate and strip construction is shown in Figs. 1, 2, and 3. Fin elements are built up from thin channel sections of copper which interlock into one another to give rigidity to the structure prior to soldering. The fins are formed by slitting the web of the channel at intervals corresponding to the fin width b , and then offsetting each alternate strip. This gives an arrangement of fins staggered by two's.

Somewhat different methods of construction were employed in the cores tested by the other authors. Norris and Spofford had each fin element consisting of a separate strip of copper. London and Ferguson's cores were made by folding a strip of aluminum back and forth to form a serpentine pattern of fin elements resembling the filler elements of corrugated fiberboard. These variants of fin construction result in only second-order effects in performance.

A radically different arrangement is described by Trumpler and Dodge. The cores, which were developed by Prof. S. C. Collins, consisted of a multiple-annulus tube in which each annulus was packed with closely coiled copper ribbon, soldered to the tube walls, so that a rather complex fin pattern resulted.

The methods which can be employed for assembling small core elements into large-size commercial units vary with the type of core and the intended service. For use in low-temperature plants (oxygen, liquid air, etc.), the following requirements were set for the commercial heat exchangers employing the fin pattern shown in Fig. 1:

- 1 An arrangement having a very close approach to true counterflow.
- 2 A single metallically bonded unit of reasonably large size to reduce the number of units per plant, thus eliminating excessive manifolding.
- 3 A unit capable of withstanding relatively high pressures.

After the initial units for the pilot plant under consideration were built, these parameters of design were increased by the addition of the following elements:

- 4 A structure of sufficient strength to resist operating pressures without the use of external tie rods, braces, etc.

5 A design to permit close stacking of individual units to minimize exposed surfaces.

6 A structure susceptible of being bonded into a complete unit, including end connections, in one operation.

7 A unit of relatively standardized design giving uniform performance.

8 A design eliminating all possibility of pass-to-pass leakage. The improved design is shown in Figs. 4 and 5.

DESCRIPTION OF EQUIPMENT

Core Structure—Fin Pattern. Both test cores and full-scale exchangers were built with fin elements arranged as shown in Fig. 1. Channels are nested twelve to the inch, with alternate strips offset $1/24$ in. so that a symmetrical pattern is obtained.

This fin pattern was tested with three modifications as given in Table 1.

TABLE 1 FIN PATTERNS TESTED

Core no.	Fin width, b , in.	Nominal fin length, i.e., passage height, $2x_f$, in.	Section tested
1	$1/8$	$1/4$	$3'' \times 3'' \times 3''$ core
2	$1/16$	$1/4$	$1-1/2'' \times 3''$ and full scale
3	$1/32$	$1/4$	Full scale

Test Cores and Test Equipment. Heat-transfer and pressure-drop results were obtained on test cores 1 and 2. Test core 1 was tested water to air. Description of this core is as follows:

Air side:

5 passages $1/2$ in. high and 3 in. wide \times 3 in. long
Total heat-transfer surface, $A = 4.37$ sq ft
Net open cross section, $A_c = 0.0492$ sq ft
Ratio: surface/cross section, $A/A_c = 89$

Water side: Cross-flow to air

6 passages 0.08 in. high \times 3 in. wide \times 3 in. long
Total heat-transfer surface 0.657 sq ft

This core was made up with the 3 in. \times 3 in. fin slabs soldered into individual units. These slabs were then separated with U-shaped brass strips soldered in place along the front edges so that the water passage was, in effect, a flat tube 3 in. \times 0.080 in. There was thus one water tube between each $1/2$ -in. air passage.

Test core 2 of the following description was tested steam to air:

Air side:

1 passage $1/2$ in. high \times 6 in. wide \times 3 in. long
Total heat-transfer surface, $A = 1.70$ sq ft
Net open cross section, $A_c = 0.0191$ sq ft
Ratio: Surface/cross section, $A/A_c = 89$

Steam side:

2 passages same as air side, except 3 in. wide \times 6 in. long

For heat-transfer tests, core lengths in the direction of air flow were kept small in order to maintain sufficiently high temperature differences between steam and discharge air; for example, an 18-in. length would have resulted in about 0.1 deg F temperature difference, too low for accurate interpretation.

The arrangement of the test stand is shown in Fig. 6. Air flow was measured by a special orifice chamber which had been calibrated by volumetric displacement. Inlet and discharge-air temperatures were measured with unshielded copper-constantan thermocouples inserted in the middle of wooden ducts, the walls of which were close to the air temperature. An excess of steam was passed through the core in order to insure uniformly high rates of heat transfer by condensation with absence of sub-cooling.

No mixing baffles or straightening vanes were used in the inlet or discharge connections, since the large number of fins in series

effected adequate mixing. Flow was fully turbulent in all tests. Reynolds number in the ducts ranged from 4000 to 40,000. A thermocouple, attached to the separating wall of test core no. 2, was used to measure wall temperatures. These values ranged from 0.5 to 1.3 deg F lower than condensing-steam temperatures. The wall temperature in the test of core 1 was calculated on the basis of waterside coefficient being given by

$$hD/k = 0.023 (DG/\mu)^{0.8} (c_p \mu/k)^{1/4}$$

Large Units and Test Equipment. For convenience in manufacturing and subsequent handling, the finned length of the large units was made 7 1/2 ft. Two types of exchangers were built, each suited to its special application in the oxygen pilot plant. The low-pressure type has equal areas for flow of the two streams since they are both at approximately atmospheric pressure, and the flow quantities are about equal. The high-pressure type has twice as much flow area for the gas at atmospheric pressure as for the one at 6 atm. This pattern results in economy of exchanger volume.

The heat exchangers were built in sections of seven passages, and then the required number of sections were bonded together to make up the final unit. Each section consists of an outer brass plate, a layer of copper fins, a brass separating plate, another layer of fins, another separating plate, and so on, for seven layers of fins, with a final outer plate. The entire assembly was soldered together in a special oven.

For the low-pressure exchangers, the inner passages consist of 1/2-in. fins, and the two outer passages of 1/4-in. fins, as illustrated in Fig. 7(a). This results in a material balance across

FIG. 7 ARRANGEMENT OF HEAT-EXCHANGER PASSAGES

each separating plate so that heat need be transferred only from the middle of any one passage to the separating plate. Were an even number of passages of equal height used, then, in the outer passages, the heat flow would have to take place across the full passage height which would mean a lower fin effectiveness, the length of the fin then being taken as 1/2 in. for calculating fin effectiveness instead of 1/4 in.

For the high-pressure exchangers having a smaller flow area for the high-pressure stream, there are in each slab section three passages for the high-pressure stream, each passage being 1/4 in. high; and for the low-pressure stream, two 1/2-in. plus two 1/4-in. passages as shown in Fig. 7(b).

In the later improved design, the size of the individual slab sections is larger and each slab is provided with standard sweat-solder-type end connections so that each slab becomes a complete heat exchanger. Any number of these individual exchang-

can be connected in parallel simply by connecting them to suitable manifolds. Such an assembly is shown in Fig. 5.

A list of the physical characteristics of the low-pressure exchangers which are called the "clean-up" exchangers is given in Table 2. The term clean-up is used because in operation, water, carbon dioxide, and hydrocarbons from the air are deposited on the metal surfaces as a rime and then removed or "cleaned up" with a stream of warmer nitrogen every 4 hr.

TABLE 2 PHYSICAL CHARACTERISTICS OF LOW-PRESSURE EXCHANGERS

Nitrogen passages (for a single exchanger):	
18 passages 1/4 in. high X 12 in. wide X 90 in. long	
Total heat-transfer surface, A	= 1858 sq ft
Net open cross section, A _c	= 0.70 sq ft
Ratio: surface/cross section, A/A _c	= 2655
Fin perimeter ψ	= 354 per ft of length
$D_e = 4r/f$	= 0.0166 ft
Air passages (for a single exchanger):	
12 passages 1/4 in. high X 12 in. wide X 90 in. long	
Plus 12 passages of 1/4 in. high X 12 in. wide X 90 in. long; for purpose of heat-transfer and pressure-drop calculations, set is considered as 18 passages, 1/4 in. high, i.e., identical with nitrogen passages	

There are four units of this type, identified as C-1, C-2, D-1, and D-2. Two of these units, C-1 and C-2, in one set and D-1 and D-2 in the other set, are operated in series.

There are two sets of high-pressure heat exchangers termed A and B. The B exchanger consists of two 7.5-ft units, each having the dimensions given in Table 3.

TABLE 3 PHYSICAL CHARACTERISTICS OF HIGH-PRESSURE EXCHANGERS

Low-pressure side:	
The same as the air passages of the clean-up exchangers	
High-pressure side:	
18 passages 1/4 in. high X 12 in. wide X 90 in. long	
Total heat-transfer surface, A	= 1,019 sq ft
Net open cross section, A _c	= 0.388 sq ft
Ratio: surface/cross section, A/A _c	= 3020
a/s	= 403 per ft of length

The A exchanger consists of a single 7.5 ft unit identical in every respect to the B units, except that the A unit has only one third the number of passages as the individual B units and therefore one third the surface area and net open area. The value of the ratio A/A_c is the same in both A and B exchangers.

Temperatures were measured with copper-constantan thermocouples which had been calibrated in an ice bath against mercury-in-glass thermometers and by immersion in boiling oxygen of 99.5 per cent purity. The thermocouples were soldered to the ends of thin-wall stainless-steel tubes which were inserted into the inlet and outlet ducts.

The thermocouple leads were carried without intermediate junctions to a Brown electronic indicating potentiometer, having a response time of about 4 sec. Therefore a complete record of temperature conditions in an exchanger could be taken in less than 1 min.

TEST RESULTS

Core Tests. Core-test results are given in Table 4. Values of f and j obtained with the first sample having 1/4-in-wide strip fins were slightly higher than reported by Norris and Spofford (1), as shown in Fig. 8. Tests of the second sample with 3/32-in-wide fins gave, over most of the range, lower values of j and higher values of f than predicted by the tests of Norris and Spofford (1). The results with 3/32-in. fins were confirmed by the tests of Kays and London (6) made on core sample 9 3/4 in. X 8 1/4 in. X 3.844 in. air-flow length, as shown in Fig. 9. The values of friction factor obtained by Kays and London at the low flows (hence low pressure drops) are believed to be more reliable and are the values used in the construction of Fig. 8.

The plotted values of the Norris and Spofford tests are shown lower than given in their paper. They used a surface area of the full fin surface plus one half the direct surface. In the present paper and in the work of London and Ferguson (4), the area is considered the full fin surface plus the full direct surface. Either method of representation is, of course, purely arbitrary.

The effective diameter to be employed for calculating Reynolds number is different in the two plots. Norris and Spofford proposed the fin perimeter, $\psi = 2(b + \delta)$ as a suitable correlating term. London and Ferguson pointed out that this is inadequate to cover all types of surface, and suggested that representation be made on the basis of the mean hydraulic diameter, $D_e = 4A_c/(A/L)$. There is probably no simple method of representation which will show the effect on performance of fin size, shape, passage spacing, etc.

Failure to realize improvement in j -values for the fins of reduced perimeter (as predicted by the Norris and Spofford correlation) is apparently due to the corresponding reduction in distance between in-line surfaces.

The values of friction factor f , obtained with all test cores, were higher than predicted by Norris and Spofford, as shown in Fig. 8. This may be attributed to difference in thickness of fins and condition of leading edges. Fin dies were of a preliminary nature and did not produce fin edges completely free of burr.

Performance of Assembled Heat Exchangers. The assembled heat exchangers were tested as part of the operation of the oxygen

pilot plant. Comparison of performance between assembled units and test cores is presented in Figs. 10 and 11. The reasonably good agreement of heat-transfer performance indicates that inefficiencies introduced when building up from test core to large-scale assembly are of small magnitude. The apparently poorer results indicated on the low-pressure clean-up exchangers may be attributed partly to errors in thermocouple readings and partly to a real decrease in efficiency due to non-uniform flow distribution. These exchangers have different-type end connections than the high-pressure exchangers, so that there may be a difference in the pattern of flows down the passages. An unbalance in flow of 2 per cent from one side of an exchanger passage to the other side results in an increase in end-temperature difference of 5.2 per cent, which represents just that much poorer performance. This lack of good flow balance is likely to be the only reason for poorer heat-transfer results in large-scale units.

Heat balances of the exchangers were made as part of the check of the over-all plant performance. In view of the extremely small end-temperature differences, such heat balances can only check the order of magnitude of the calculated performance.

Table 6 is a sample sheet showing the step-wise method of calculating the performance of exchanger B. A discussion of the factors involved is given in the Appendix. The variation of temperature with length of the heat exchanger is shown graphically in Fig. 12.

The over-all pressure drops measured on the assembled heat exchangers are greater than those predicted from results on test cores as may be seen from Fig. 11, showing friction factor plotted against Reynolds number. This higher pressure drop is attributed to losses in the end connections, the magnitude of which can only be estimated from the observed over-all performance. The end connections which provide for distribution of the flow from the relatively narrow inlet nozzle to the full width of the exchanger slab are built up of a number of hollow rectangular tubes placed in the form of a grid. These tubes support the separating plates, at the same time permitting flow to take place in two directions. The arrangement of these spacer tubes is shown in Fig. 13. For the clean-up exchangers, the "low-pressure-pass" arrangement is used on both air and nitrogen passes. For the high-pressure exchangers A and B, the arrangements are as indicated, respectively, for the two sets of passes.

Table 7 gives typical pressure-drop results for the pilot-plant

FIG. 13 PATTERNS OF SPACER TUBES IN END MANIFOLDS OF HEAT EXCHANGERS

ACKNOWLEDGMENTS

The successful construction of these heat exchangers is due largely to the untiring efforts of Mr. Don Huggins, Mechanical Engineer at Modine Manufacturing Company, who supervised exchanger assembly. Core tests were the work of Mr. Huggins and Modine laboratory technicians. Performance values on the large heat exchangers were obtained by the plant engineers responsible for the design and operation of the Elliott Company oxygen pilot plant, Messrs. Duffer Crawford, Joseph Cost, Carroll Claitor, and Mack Atcheson.

The authors also wish to express their appreciation of the contribution of Modine Manufacturing Company and the Elliott Company who underwrote this project and agreed to publication of the results.

Appendix

CALCULATION OF EXCHANGER PERFORMANCE

The method of stepwise calculation of exchanger performance has been developed as follows:

For each set of passages of incremental length, Δl ; the incremental NTU is

$$\Delta NTU_h = \frac{\delta t_h}{\Delta t_h} = \frac{j_h (a/s)_h (\Delta l)}{0.818}$$

$$\Delta NTU_c = \frac{\delta t_c}{\Delta t_c} = \frac{j_c (a/s)_c (\Delta l)}{0.818}$$

where

δt_h = temperature change of hot fluid over length of exchanger

$\Delta t_h = t_h - t_m$ = temperature difference between hot fluid and metal wall

$\Delta t_c = t_m - t_c$ = temperature difference between metal wall and cold fluid

$t_h - t_c$ = temperature difference between two gases

a/s = ratio of total surface to net open area per unit of length

The equations for NTU are applicable over a short length for which the conditions of physical properties and temperature differences between the two gases are essentially constant. The performance for the full exchanger length is obtained by adding up the NTU for each elemental length.

The over-all NTU can be determined as a ratio of the NTU for either of the two streams:

For the hot stream

$$NTU_h = \frac{\delta t_h}{t_h - t_c} = \frac{\delta t_h}{\Delta t_h + \Delta t_c}$$

For the cold stream

$$NTU_c = \frac{\delta t_c}{t_h - t_c} = \frac{\delta t_c}{\Delta t_h + \Delta t_c}$$

Arbitrarily, the over-all NTU , based on the hot stream, will be used for calculating the exchanger performance. The final answer would be identical were the NTU based upon the cold stream. For the NTU based on the hot stream

$$NTU_h = \frac{\delta t_h}{t_h - t_c} = \frac{j_h \eta_h (a/s)_h (\Delta l) (\Delta t_h)}{(\Delta t_h + \Delta t_c) (0.818)}$$

To find the value of the ratio $\Delta t_h / (\Delta t_h + \Delta t_c)$ in terms of the known physical characteristics and temperature changes

$$\Delta t_h = \frac{\delta t_h (0.818)}{j_h \eta_h (a/s)_h (\Delta l)}$$

$$\Delta t_c = \frac{\delta t_c (0.818)}{j_c \eta_c (a/s)_c (\Delta l)}$$

$$\frac{\Delta t_h}{\Delta t_h + \Delta t_c} = \frac{\delta t_h (0.818)}{[j_h \eta_h (a/s)_h (\Delta l)] \left[\frac{\delta t_h (0.818)}{j_h \eta_h (a/s)_h (\Delta l)} + \frac{\delta t_c (0.818)}{j_c \eta_c (a/s)_c (\Delta l)} \right]}$$

which simplifies to

$$\frac{\Delta t_h}{\Delta t_h + \Delta t_c} = \frac{\delta t_h}{\delta t_h + \delta t_c \left(\frac{j_h}{j_c} \right) \left(\frac{\eta_h}{\eta_c} \right) \left[\frac{(a/s)_h}{(a/s)_c} \right]}$$

Substituting the value of this ratio in the equation for NTU

$$NTU_h = \frac{\delta t_h}{t_h - t_c} = \frac{j_h \eta_h (a/s)_h (\Delta l) (\delta t_h)}{0.818 \left[\delta t_h + \delta t_c \left(\frac{j_h}{j_c} \right) \left(\frac{\eta_h}{\eta_c} \right) \left(\frac{a/s)_h}{(a/s)_c} \right] \right]}$$

Rearranging this equation

$$\Delta l = \frac{(0.818) \left[\delta t_h + \delta t_c \left(\frac{j_h}{j_c} \right) \left(\frac{\eta_h}{\eta_c} \right) \left(\frac{a/s)_h}{(a/s)_c} \right] \right]}{j_h \eta_h (a/s)_h (t_h - t_c)}$$

The ratio of the two heat-transfer factors is a function of the modified Reynolds number to the 0.4 power (as indicated by test-core results)

$$\frac{j_h}{j_c} = \frac{0.245 / (D_e G / \mu)_h^{0.4}}{0.245 / (D_e G / \mu)_c^{0.4}}$$

The value of the effective diameter D_e for the two streams is taken as being equal.

The viscosities of the two gases, hot gas and the cold gas, within the same small increment of length, under conditions of operation, may be considered equal; hence

$$\frac{j_h}{j_c} = \left(\frac{G_h}{G_c} \right)^{0.4}$$

Then

$$\Delta l = \frac{(0.818) \left[\delta t_h + \delta t_c \left(\frac{G_h}{G_c} \right)^{0.4} \left(\frac{\eta_h}{\eta_c} \right) \left(\frac{a/s)_h}{(a/s)_c} \right] \right]}{j_h \eta_h (a/s)_h (t_h - t_c)}$$

The calculation of exchanger performance can be handled by relating the performance at any section (and any temperature) to the performance at an arbitrary temperature. This arbitrary standard temperature is taken as 100 F. The ratio of performance is given by

$$\frac{j_{100}}{j_t} = \frac{0.245 / (D_e G_{100} / \mu_{100})^{0.4}}{0.245 / (D_e G_t / \mu_t)^{0.4}}$$

Since D_e and G are constant along the length of the exchanger

$$j_{100} / j_t = (\mu_{100} / \mu_t)^{0.4}$$

Substituting the value of $(j_h)_{100}$ in the equation for performance

$$\Delta l = \frac{0.818 \left[\delta t_h + \delta t_c \left(\frac{G_h}{G_c} \right)^{0.4} \left(\frac{\eta_h}{\eta_c} \right) \left(\frac{a/s)_h}{(a/s)_c} \right] \right]}{(j_h)_{100} \left(\frac{\mu_t}{\mu_{100}} \right)^{0.4} \eta_h (a/s)_h (t_h - t_c)}$$

From this equation the incremental length for each temperature range can be calculated and then the value of $(j_h)_{100}$ determined from the conditions in any particular interval of length. The method of calculating performance is illustrated by the following example:

Exchanger B is handling a flow of 4220 lb per hr of nitrogen in the high-pressure passages and 4270 lb per hr in the low-pressure passages. The respective average pressures are 85 psia and 18 psia. The observed end temperature conditions are as follows:

	Temperature, deg F		
	High pressure	Low pressure	Difference
Warm end.....	85	78.5	6.5
Cold end.....	-256.5	-276.7	20.2
Temperature change	341.5	355.2	

FIG. 15 NET JOULE-THOMSON ΔT

The detailed calculations are handled in tabular form as shown, in Table 6. The multiplier for the temperature change Δt_c of the cold fluid is

$$\left(\frac{G_c}{G_h}\right)^{0.4} \frac{\eta_h (a/s)_h}{\eta_c (a/s)_c} = \left(\frac{6100}{12,500}\right)^{0.4} \left(\frac{0.967}{0.922}\right) \left(\frac{403}{354}\right) = 0.896$$

The ratio of fin effectiveness for the hot fluid to that of the cold fluid at 100 F is 0.967/0.922 and is taken as being constant over the entire length of the exchanger. Variation of this ratio with temperature is negligible.

The first five columns of the table are used to calculate a heat balance over each incremental length. The balance could be made by taking enthalpy values from a temperature-enthalpy chart or table but as a practical method the scheme shown is

easier to handle. The high-pressure temperature is split into convenient intervals with the first increment taken as small as 2 deg in order to reduce the effect of averaging in using this interval for calculating the value of j_{100} . The net Joule-Thomson effect (7) is the difference between the Joule-Thomson effect at an arbitrary temperature (taken at 100 F) and the Joule-Thomson effect at the particular temperature interval. Values are plotted in Fig. 15. The adjustment for unbalance flow is calculated by allowing a higher or lower temperature change for the low-pressure stream than for the high-pressure stream, inversely proportional to the difference of the two molal flows. The column next to the last is calculated as an incremental length which is converted to actual incremental lengths in the last column.

The value of the heat-transfer factor at 100 F is then calculated by using the performance values over any increment of length

$$j_{100} = \frac{0.818 \left[\Delta t_h + (\Delta t_c) \left(\frac{G_c}{G_h} \right)^{0.4} \frac{\eta_h (a/s)_h}{\eta_c (a/s)_c} \right]}{\Delta l \left(\frac{\mu_t}{\mu_{100}} \right)^{0.4} \eta_h (a/s)_h (t_h - t_c)}$$

Substituting the values from the table for the interval 85 deg to 83 deg

$$j_{100} = \frac{0.818 [2 + 2(0.896)]}{(0.1192)(0.993)(0.967)(403)(6.5)} = 0.0104$$

Reynolds number at 100 deg F for the given conditions of flow is

$$D_s G/\mu = (0.0117)(12,500)/(0.044) = 3320$$

From the temperature and incremental length values in Table 6, the change of temperature along the length of the exchanger can be plotted, as has been done in Fig. 12.

Design of Regenerators for Gas-Turbine Service

By DAVID ARONSON¹

This paper presents a method for designing gas-turbine regenerators with particular reference to the condition of space being the principal limitation on design. For the plate-fin structure a procedure is given for arriving at maximum performance attainable in a given volume of regenerator core, and for calculating the fin patterns and plate spacings required to obtain such maximum performance. For the tubular-type regenerator a method of arriving at optimum tube spacings is presented.

NOMENCLATURE

- A = heat-transfer area, sq ft
 a = factor in determining fin effectiveness, $a = (2h/kt)^{0.5}$
 B = constant $\frac{j/(f/2)_g \eta_g R L_c^2}{(NTU)(W_g v_g)^2 (Pr)^{1/2}}$
 b = wetted perimeter, ft
 c = fraction of total length, L_c , given to cold stream:
 $L_c(c)$ = total height in no-flow direction of all cold-stream passages, ft
 $L_c(1 - c)$ = total height in no-flow direction of all hot-stream passages, ft
 c_p = specific heat at constant pressure, Btu/(lb F)
 C = air or gas capacity rate, $C = W c_p$, Btu/(hr F)
 C_2, C_3, C_4, C_5 = constants related to f, j , and $j/(f/2)$
 C_7, C_8, C_9 = constants relating performance inside to outside of tubes
 D_e = equivalent diameter of passage, for rectangular passages, ft
 $D_e = 4r_h = \frac{4S}{b} = \frac{4(D_1 D_2)}{2(D_1 + D_2)} = \frac{2D_1 D_2}{D_1 + D_2}$
 D_1 = width of rectangular passage, ft or in.
 D_2 = height of rectangular passage, ft or in.
 D_i = inside diameter of round tubes, ft or in.
 D_o = outside diameter of round tubes, ft or in.
 F = ratio of design factors, dimensionless (see text)
 f, f_g = see dimensionless groupings
 G = mass velocity, lb/(hr ft²) or lb/(sec ft²) $G = V\rho$ or V/v
 G_o = mass velocity at minimum opening between tubes, lb/(hr ft²) or lb/(sec ft²)
 g = proportionality factor, $g = 32.2$ lb ft/# sec² = 4.17×10^4 lb ft/# hr²
 h = unit conductance for thermal convection heat transfer, Btu/(hr ft² F)

- j = see dimensionless groupings
 k = thermal conductivity, Btu/(hr ft² F/ft)
 L = flow length, ft
 L_a = length of passage for flow of gas, ft
 L_b = length of passage for flow of air, ft
 L_c = length of assembly of passages in no-flow direction for crossflow plate-fin type exchanger, or length in no-flow direction for tubular exchanger, ft
 L_n = dimension in direction of stream flowing across outside of tubes, ft
 L_T = length of tubes, ft
 N = number of tubes in direction of flow across tubes, dimensionless $N = L_n/S_L$
 NTU = see dimensionless groupings
 P = pressure, #/in.² or #/ft²
 $(\Delta P/P)$ = pressure-drop ratio, dimensionless
 R = gas constant; for air $R = 53.3$ ft #/(lb F)
 r = ratio of volume flow of two streams, dimensionless
 $r = \frac{(W/\rho)_a}{(W/\rho)_g} = \frac{W_a v_a}{W_g v_g}$
 r_h = hydraulic radius, ft
 S = free flow area, sq ft
 S_T/D_o = tube-spacing ratio, center to center in direction normal to gas flow, dimensionless
 S_L/D_o = tube-spacing ratio, center to center in direction of gas flow, dimensionless
 T = temperature, R
 t = temperature, F
 Δt_{lm} = long mean temperature difference, F
 $t_{lm} = \frac{[(t_1)_g - (t_2)_a] - [(t_2)_g - (t_1)_a]}{\ln \left[\frac{(t_1)_g - (t_2)_a}{(t_2)_g - (t_1)_a} \right]}$
 Δt_m = mean-effective-temperature difference to be used in determining efficiency for crossflow heat exchangers, F
 $\Delta t_m = Y(\Delta t_{lm})$
 $\Delta t_m = (\Delta t_m)_g + (\Delta t_m)_a$
 $(\Delta t_m)_a$ = mean-effective-temperature difference between air and metal wall
 $(\Delta t_m)_g$ = mean-effective-temperature difference between gas and metal wall
 Δt_o = difference between bulk fluid temperature and temperature of metal wall at base of fin
 δt = change in temperature of fluid going through regenerator, F, $\delta t = t_1 - t_2$
 U = unit over-all thermal conductance, Btu/(hr ft² F of A)
 V = velocity of fluid, at average air or gas temperature, fps
 v = specific volume, at average air or gas temperature, ft³/lb

W = flow rate, lb/sec or lb/hr

x_f = effective length of fin

Y = correction factor to apply to log-mean-temperature difference to obtain effective temperature difference, dimensionless

$$Y = \Delta t_m / \Delta t_{lm}$$

from which $NTU = \delta t / (Y \Delta t_{lm})$

Values of Y are summarized on page 147 of (15)² from report of Bowman, Mueller, and Nagle (16).

δ , Δ = prefixes denoting difference

ϵ = heat-exchanger effectiveness, a function of NTU , C_a/C_g , and flow arrangement, dimensionless (see Fig. 2)

$$\epsilon = \frac{(t_2)_a - (t_1)_a}{(t_2)_g - (t_1)_a} = X \text{ of McAdams (15)}$$

η = combined fin and metal-wall effectiveness, dimensionless

$$\eta = \eta_s \frac{D_2}{D_1 + D_2} + 1.00 \frac{D_1}{D_1 + D_2}$$

η_s = fin effectiveness, dimensionless

$$\eta_s = \frac{\tanh ax_f}{ax_f}$$

ν = absolute viscosity, lb/(hr ft)

ρ = fluid density, lb/ft³

σ = ratio of free flow to frontal area, dimensionless

Dimensionless Grouping

A/S = ratio of surface area to net open area. $A/S = 4L/D_s$

$f = \frac{(\Delta P)(\nu)}{(V^2/2g)(A/S)}$ = Fanning friction factor. The f versus Re plot defines the friction characteristic of the surface

$f_o = \frac{(\Delta P)(\nu)}{(V^2/2g)N}$ = friction factor for flow across tubes. The

f_o versus Re plot defines the friction characteristic of the tube pattern. The velocity, V , is that at the minimum opening between tubes and N is the number of such openings in the direction of flow

f_o is related to f by:

$$f_o \frac{(S_T/D_o - 1)}{\pi/4} = \phi \approx f$$

$j = (St)(Pr)^{1/4}$ = generalized heat-transfer grouping. This factor, j versus Re , defines the heat-transfer characteristic of the surface

NTU = number of core "heat-transfer units," a dimensionless expression of the "heat-transfer size" of the core. NTU is customarily based on the minimum weight flow.

$$NTU = UA/C_{min} = \frac{\delta t_a}{\Delta t_m}$$

$$= \frac{\text{Temperature change of air}}{\text{Over-all mean-temperature difference}}$$

² Numbers in parentheses refer to the References at end of the paper.

$NTU_a = NTU$ for the air side of the core. $NTU_a = \eta_a h_a A_a / C_a$

$$= j_a (Pr)^{-1/4} \eta_a (A/S)_a = \frac{\delta t_a}{(\Delta t_m)_a}$$

$NTU_g = NTU$ for the gas side of the core

$$NTU_g = \eta_g h_g A_g / C_g = j_g (Pr)^{-1/4} \eta_g (A/S)_g = \frac{\delta t_g}{(\Delta t_m)_g}$$

$Pr = (C_p \mu / k)$, Prandtl number, a fluid property modulus

$Re = (DG/\mu)$, Reynolds number, a flow property modulus characterizing the "turbulence"

$St = (h/\dot{G}c_p)$, Stanton's number, a heat-transfer modulus

$\phi = \frac{(\Delta P)(\nu)}{(V^2/2g)(A/S)}$ friction factor for flow across tubes based on ratio of surface area to minimum open area

Subscripts

a = air-side condition

g = gas-side condition

i = condition on inside of tube

o = condition on outside of tube

1 = fluid entrance condition to heat exchanger

2 = fluid condition at exit of heat exchanger

Miscellaneous

lb = pounds mass in distinction to

= pounds force

INTRODUCTION

This paper develops a design procedure for the gas-turbine regenerator. It is particularly applicable to those installations where space available for the regenerator is limited. Both the extended surface, plate-fin type, and the tubular type are considered.

In regenerator design there is an optimum ratio between the heat-transfer coefficients and surface areas on the cold side to those on the hot side which will result in the lowest over-all pressure drop $\Delta P/P$ for a given regenerator effectiveness ϵ . In the past this ratio was arrived at by tedious trial-and-error calculations. By using the relationships developed in this paper the designer may reduce the number of such trials or eliminate them completely. Further aid in design is to be found in the work of Soderberg and Smith (1) which shows the effect of regenerator thermal effectiveness on cycle efficiency, and in the paper of London and Kays (2) which is a comparison of several types of heat-transfer surfaces for regenerator application.

GENERAL DESIGN PROCEDURE

The design of a gas-turbine regenerator is simplified if one works mainly with dimensionless ratios. The two important ratios are:

$$\frac{\delta t}{\Delta t_m} = \frac{\text{Temperature change of one fluid}}{\text{Over-all mean temperature difference between one fluid and the other}}$$

$$\frac{\Delta P}{P} = \frac{\text{Pressure drop of fluid going through regenerator}}{\text{Absolute pressure of fluid}}$$

By simple for heat t relations obtains ed of the rege A balan and the fo

This ratio tor j and

Substitu gives

A simila The p given by

and by the dim

and sir

For cu be tak withou Equ ship b

The v passa 5000 proxi

By simple algebraic rearrangement of the well-known expressions for heat transfer and pressure drop, it is possible to develop the relationship between these two ratios. At the same time one obtains equations relating these ratios to the physical design of the regenerator.

A balance between the quantity of heat to be transferred and the force producing the transfer is given by

$$W c_p \Delta t = U A \Delta t_m \dots \dots \dots [1]$$

which can be rearranged to

$$U A / W c_p = \Delta t / \Delta t_m \dots \dots \dots [2]$$

This ratio of temperature change to temperature difference is expressed as NTU , number of transfer units. The performance on each side of the regenerator may be expressed similarly. For the gas side

$$W_g (c_p)_g (\delta t)_g = h_g \eta_g A_g (\Delta t_m)_g \dots \dots \dots [3]$$

which rearranges to

$$NTU_g = \frac{(\delta t)_g}{(\Delta t_m)_g} = \frac{h_g \eta_g A_g}{W_g (c_p)_g} = \frac{h_g \eta_g A_g}{C_g} \dots \dots \dots [4]$$

This ratio can be calculated directly from the heat-transfer factor j and the ratio of surface to net open area A/S

$$j = \frac{h}{G c_p} \left(\frac{c_p \mu}{k} \right)^{1/4} = \frac{h}{(W/S) c_p} \left(\frac{c_p \mu}{k} \right)^{1/4} \dots \dots \dots [5]$$

Substitution of the value of j from Equation [5] in Equation [4] gives

$$NTU_g = \frac{j_g (A/S)_g \eta_g}{(c_p \mu / k)^{1/4}} \dots \dots \dots [6]$$

A similar development applies to the air side.

The pressure drop for flow in tubes or continuous passages is given by

$$\Delta P = \frac{f V^2 (A/S)}{2 g v} \dots \dots \dots [7]$$

and by dividing through both sides by the absolute pressure P , the dimensionless form is obtained

$$\Delta P / P = \frac{f V^2 (A/S)}{2 g P v} \dots \dots \dots [8]$$

and since

$$P v = R T$$

$$\Delta P / P = \frac{f V^2 (A/S)}{2 g R T} \dots \dots \dots [9]$$

For conditions in a regenerator the values of P , v , and T may be taken as the arithmetic average of inlet and outlet conditions without introducing significant error.

Equations [6] and [9] may be combined to give the relationship between NTU and $\Delta P / P$

$$NTU_g = \frac{[j/(f/2)]_g (\Delta P / P)_g g R T_g \eta_g}{V_g^2 (C_p \mu / k)^{1/4}} \dots \dots \dots [10]$$

The value of $j/(f/2)$ is a function of both Reynolds number and passage geometry. For flow through round tubes at Re from 5000 to 200,000 the values of f and j , respectively, may be approximated by

$$f = 0.046 / Re^{0.2}$$

$$j = 0.023 / Re^{0.2}$$

REGENERATOR

FIG. 1 ARRANGEMENT OF SURFACES IN PLATE-FIN-TYPE REGENERATOR

so that

$$j/(f/2) = 1.0$$

At values of Re less than 5000 this ratio becomes less than unity and is dependent on the length-to-diameter ratio of the passage. Test values of different types of fins are reported in (3), (4), (5), (6), and (7). For the type of construction here considered, the values of $j/(f/2)$ vary from about 0.5 to 1.0. (See Fig. 1.)

A Relationship Between Individual and Over-All Performance Values.

The reciprocals of the NTU_g and NTU_a may be added to give the reciprocal of the over-all NTU , shown as follows

$$\frac{1}{UA} = \frac{1}{h_g A_g \eta_g} + \frac{1}{h_a A_a \eta_a} \dots \dots \dots [11]$$

In a gas turbine the weight flows and the heat capacities of the two streams are approximately equal so that

$$C_g = C_a \dots \dots \dots [12]$$

Dividing Equation [11] by [12]

$$\frac{1}{UA} = \frac{1}{h_g A_g \eta_g} + \frac{1}{h_a A_a \eta_a} \dots \dots \dots [13]$$

which from Equations [2] and [4] is identical with

$$\frac{1}{NTU} = \frac{1}{NTU_g} + \frac{1}{NTU_a} \dots \dots \dots [14]$$

Where no subscript is used, NTU will be read as the over-all number of transfer units. The over-all NTU can be related to the individual pressure-drop ratios by substituting Equation [10] in [14]

$$\frac{1}{NTU} = \frac{(V_g)^2 (Pr)^{1/2}}{j/(f/2)_g \eta_g (\Delta P/P)_g gRT_g} + \frac{(V_a)^2 (Pr)^{1/2}}{j/(f/2)_a \eta_a (\Delta P/P)_a gRT_a} \quad [15]$$

The individual pressure-drop ratios can be shown by thermodynamic analysis to have an effect on the cycle proportional to their sum

$$\Delta P/P \approx (\Delta P/P)_g + (\Delta P/P)_a \quad [16]$$

This develops from the expression for the entropy gain due to pressure loss which is given by

$$-R \ln (P_2/P_1)$$

where P_1 is the pressure at the inlet to the regenerator and P_2 is the pressure at the outlet. For the small pressure ratios involved in regenerator design the logarithm of the ratio may be approximated by

$$\ln P_2/P_1 = \ln (1 - \Delta P/P_{avg}) = -\Delta P/P_{avg}$$

B Optimum Relations Between Performance in Air and in Gas Passages.

There are optimum ratios between the individual NTU and the individual $\Delta P/P$ which give the highest over-all NTU for a given $\Delta P/P$, or for a given NTU , the lowest total $\Delta P/P$. Partial differentiation with respect to the possible variables and setting the resulting partial differentials equal to zero gives the optimum conditions.

The following relationships are developed in order to arrive at equations suitable for differentiation

$$V_g = (W_g v_g)/S_g \quad [17a]$$

$$V_a = (W_a v_a)/S_a \quad [17b]$$

Let

$$r = (W_a v_a)/(W_g v_g) \quad [18]$$

and

$$L_c(c) = \text{length in ft in no-flow direction given to cold-stream passages} \quad [19a]$$

$$L_h(1-c) = \text{length in ft in no-flow direction given to hot-stream passages} \quad [19b]$$

The space occupied by metallic separating walls is neglected. The areas for flow are, respectively

$$S_g = (L_h)(L_c)(1-c) \quad [20]$$

$$S_a = (L_h)(L_c)(c) \quad [21]$$

Substituting Equations [18], [19a], and [19b], in Equations [17a] and [17b] gives

$$V_g = \frac{(W_g v_g)}{(L_h)(L_c)(1-c)} \quad [22]$$

$$V_a = \frac{(W_a v_a)}{(L_h)(L_c)(c)} = \frac{r(W_g v_g)}{(L_h)(L_c)(c)} \quad [23]$$

Inserting these values of V in Equation [15]

$$\frac{1}{NTU} = \frac{(W_g v_g)^2 (Pr)^{1/2}}{j/(f/2)_g \eta_g (\Delta P/P)_g gRT_g (L_h)^2 (L_c)^2 (1-c)^2} + \frac{r^2 (W_g v_g)^2 (Pr)^{1/2}}{j/(f/2)_a \eta_a (\Delta P/P)_a gRT_a (L_h)^2 (L_c)^2 (c)^2} \quad [24]$$

To simplify the analysis one can assume that the following terms are equalities (which is approximately true)

$$j/(f/2)_g = j/(f/2)_a$$

$$\eta_g = \eta_a$$

$$(Pr)_g^{1/2} = (Pr)_a^{1/2}$$

and that the change in value of $j/(f/2)$ in the range of possible design variations may be considered a second-order effect. Let

$$\frac{j/(f/2)_g R L_c^2}{(NTU) (W_g v_g)^2 (Pr)^{1/2}} = B$$

then Equation [24] becomes

$$B = \frac{1}{(\Delta P/P)_g T_g L_h^2 (1-c)^2} + \frac{r^2}{(\Delta P/P)_a T_a L_h^2 c^2} \quad [25]$$

Let

$$F = NTU_g/NTU_a \quad [26]$$

$$F = \frac{1/NTU_g}{1/NTU_a} = \frac{(\Delta P/P)_a T_a L_h^2 c^2}{(\Delta P/P)_g T_g L_h^2 (1-c)^2} \quad [27]$$

Substituting Equation [27] in [25] and solving for the individual values of $\Delta P/P$ gives

$$(\Delta P/P)_g = \frac{(F+1)}{B (L_h)^2 (1-c)^2 T_g} \quad [28]$$

$$(\Delta P/P)_a = \frac{(F+1)}{(F)(B)(L_h)^2 (c)^2 T_a} \quad [29]$$

Substituting Equations [28] and [29] in Equation [16] gives the general equation

$$\Delta P/P = \frac{(F+1)}{B (L_h)^2 (1-c)^2 T_g} + \frac{(F+1) r^2}{(F) B (L_h)^2 (c)^2 T_a} \quad [30]$$

The value of F and c for minimum $\Delta P/P$ are found by partial differentiation as mentioned above

$$\left(\frac{\partial(\Delta P/P)}{\partial c} \right)_F = 0 = + \frac{(F+1) 2}{B (L_h)^2 (1-c)^2 T_g} - \frac{(F+1) 2 r^2}{(F) B (L_h)^2 c^3 T_a} \quad [31]$$

$$\left(\frac{c}{1-c} \right)^2 = \frac{(r L_h/L_a)^2 (T_g/T_a)}{F} \quad [32]$$

$$\left(\frac{\partial(\Delta P/P)}{\partial F} \right)_c = 0 = \frac{1}{B L_h^2 (1-c)^2 T_g} - \frac{r^2}{F^2 (B) (L_h)^2 (c)^2 T_a} \quad [33]$$

$$F^2 = (r L_h/L_a)^2 \left(\frac{1-c}{c} \right)^2 (T_g/T_a) \quad [34]$$

Substituting the value of F obtained from Equation [34] in Equation [32] gives

$$\frac{c}{1-c} = (r L_h/L_a)^{0.5} (T_g/T_a)^{0.25} \quad [35]$$

Substituting Equation [35] in Equation [34] gives

$$F = (r L_h/L_a)^{0.5} (T_g/T_a)^{0.25} \quad [36]$$

Comparing Equation [36] with Equation [35] one notes that

$$F = \frac{c}{1-c} \quad [37]$$

Equation [27] can be rewritten as

$$F = \frac{r^2 (\Delta P/P)_g T_g L_a^2 (1-c)^2}{(\Delta P/P)_a T_a L_a^2 (c)^2} \quad [38]$$

which combined with Equation [34] gives

$$F = \frac{(\Delta P/P)_a}{(\Delta P/P)_g} \quad [39]$$

These relationships can be more readily visualized by equating them all to F .

$$F = \frac{(\Delta P/P)_a}{(\Delta P/P)_g} = \frac{c}{1-c} = \frac{(D_2)_a}{(D_2)_g} = \frac{(NTU)_g}{(NTU)_a} = \left(\frac{r L_a}{L_g} \right)^{0.5} \left(\frac{T_g}{T_a} \right)^{0.25} \quad [40]$$

$(D_2)_a$ and $(D_2)_g$ are the heights, respectively, of the cold and hot stream passages, on the basis that there is the same number of passages for both streams.

The over-all NTU can be related to the over-all pressure-drop ratio and the velocity of either stream by rearrangement of the relationships given in Equation [40]

$$NTU = \frac{(\Delta P/P)_g \eta [j/(f/2)] gRT_g}{(1+F)^2 (V_g)^2 (Pr)^{1/2}} = \frac{F^2 (\Delta P/P)_g \eta [j/(f/2)] gRT_a}{(1+F)^2 (V_a)^2 (Pr)^{1/2}} \quad [41]$$

In the foregoing analysis no allowance has been made for losses other than frictional pressure drops. These other losses are small enough as not to affect significantly the design relationships, but they should of course be included in the calculation of over-all performance.

For the general case in which

$$\begin{aligned} C_a/C_g &= Z \neq 1 \\ W_g/W_a &= M \neq 1 \\ (c_p)/(c_p)_g &= ZM \neq 1 \end{aligned}$$

the analysis is similar to that already presented, except that the ratios of the two flows must be included. The final equations so derived are

$$F = \frac{(\Delta P/P)_a}{M(\Delta P/P)_g} = \frac{NTU_g}{Z(NTU)_a} = \left[\frac{(c_p)_g}{(c_p)_a} \right]^{0.25} \left[\frac{r(L_b)}{(L_a)} \right]^{0.5} \left[\frac{T_g}{T_a} \right]^{0.25} \quad [42]$$

C Design of Exchanger Passages.

The spacings of exchanger passages can be calculated by means of Equations [6] and [40], and from plots of the j values for the particular fin design chosen. The ratio of passage heights is given by Equation [40], but the absolute value to be used is a matter of judgment on the part of the designer. He must balance high fin effectiveness against increased cost and weight as the height of individual passages is reduced. Conversely, as fin height is increased fin thickness must be maintained adequate to provide reasonable values of fin effectiveness. The fin effectiveness is given by

$$\eta_s = (\Delta t)_m/(\Delta t)_o = (\tanh ax_f)/(ax_f) \quad [43]$$

where

$$a = (hb/ks)^{0.5} = (2h/kt)^{0.5} \text{ for uniform rectangular section fin}$$

x_f = effective length of fin

This length will vary from one half the passage height to the full passage height depending on the method of assembling the individual passages. If the regenerator is built up by assembling individual flat "tubes" consisting of one gas passage and one air passage as shown in sketch B of Fig. 3, then the fin height is the full passage height. If made with one center passage for air and two half-passages for gas as shown in sketch A of Fig. 3, the fin height is taken as one half the center passage height for the air side and the height of the half-passages for the gas side. If there are an even number of passages bonded together as shown in Fig. 1, then the fin height is some value between one half and the full passage height.

The direct surface effectiveness may be taken as unity, so that the over-all effectiveness is

$$\eta = \eta_s \left(\frac{D_2}{D_1 + D_2} \right) + \left(\frac{D_1}{D_1 + D_2} \right) \quad [44]$$

The effective diameter, D_e , for smooth continuous fins may be obtained approximately by substitution in Equation [6] of the relationship between j and Reynolds number

$$NTU = j (4L/D_e) (Pr)^{-1/2} = 0.023 (Re)^{-0.2} (4L/D_e) (Pr)^{-1/2} \quad [45]$$

D Example—Over-All Performance.

The design of a regenerator for a locomotive gas turbine will illustrate the handling of the foregoing relationships:

The following are the approximate properties of the two streams (exact values not being known until the regenerator has been designed):

	Gas side	Air side
Weight flow, W , lb/sec.....	60	60
Average density, lb/ft ³	0.0333	0.166
Average specific volume, v , ft ³ /lb....	30.0	6.0
Average viscosity, μ , lb/(ft) (hr)....	0.076	0.068
Heat capacity, c_p , Btu/(lb) (F).....	0.25	0.25
Prandtl number, $c_p \mu/k$	0.67	0.67
Average temperature, T , deg R.....	1210	980
Average pressure, P , psia.....	14.9	60.0

The regenerator is to have a core of the following dimensions:

Length of flow path for hot gas, L_a , 3 ft
Length of flow path for cold gas, L_b , 7 ft
No flow direction, L_c , 6 ft

As a first step in the design one can determine the relationship between pressure-drop ratio and NTU . With this information the turbine designer can decide upon the optimum NTU for the turbine cycle.

The design parameter F is given by Equation [36]

$$F = [(0.2) (7/3)]^{0.5} (1210/980)^{0.25} = 0.72$$

(The first figure of 0.2 is obtained from $r = v_a/v_g = 6/30 = 0.2$)

Assuming that the ratio of net free area to gross cross-sectional area for the sum of the two streams ($\sigma_g + \sigma_a$) is 0.85 and that it is about proportional to the relative net free area of each, then the velocities of the gases are

$$V_a = \frac{W_a v_a}{(L_a)(L_c) \left(\frac{F}{1+F} \right) (\sigma)} = \frac{(60)(6)}{(3)(6) [(0.72)/1.72] (0.85)} = 56.2 \text{ ft/sec}$$

$$V_g = \frac{W_g v_g}{(L_g)(L_c) [1/(1+F)] (\sigma)} = \frac{(60)(30)}{(7)(6) [1/(1+0.72)] (0.85)} = 88.7 \text{ ft/sec}$$

Either of these values can be substituted in the appropriate part of Equation [41] to give the relationship between pressure-drop ratio and NTU . The following values are assumed for this preliminary study:

$$\text{Fin effectiveness, } \eta_f = 0.85$$

$$j/(f/2) = 0.75$$

The ratio of j to the half friction factor is higher than 0.75 but is reduced to allow for pressure losses at inlet and discharge and for losses or gains due to acceleration or deceleration of the fluid streams.

Based on gas stream

$$NTU_{\text{over-all}} = \frac{(\Delta P/P) (0.85) (0.75) (32.2) (53.3) (1210)}{(1.72)^2 (86.7)^2 (0.77)} = 77.2 (\Delta P/P)$$

Based on air stream

$$NTU_{\text{over-all}} = \frac{(\Delta P/P) (0.85) (0.75) (32.2) (53.3) (980) (0.72)^2}{(1.72)^2 (56.2)^2 (0.77)} = 77.2 (\Delta P/P)$$

If the $\Delta P/P$ for the cycle is limited to 3 per cent, then the maximum NTU obtainable in the given volume is

$$NTU_{\text{over-all}} = (77.2) (0.03) = 2.31$$

which for a single pass crossflow unit gives an efficiency ϵ of 64 per cent, Fig. 2.

FIG. 2 PLOT OF NTU VERSUS EXCHANGER EFFECTIVENESS

E Example Design of Passages.

The calculations to arrive at passage and fin spacings for an over-all NTU of 2.31 are as follows
From Equation [40]

$$NTU_g = (1 + F) (NTU) = (1.72) (2.31) = 3.98$$

$$NTU_a = \left(\frac{1 + F}{F} \right) (NTU) = \left(\frac{1.72}{0.72} \right) (2.31) = 5.52$$

$$F = \frac{(D_2)_a}{(D_2)_g} = 0.72$$

FIG. 3 HEAT-FLOW PATTERN IN FINNED SECTIONS

From Equation [45] the equivalent diameter of the two passages are found. Using the values of Pr and η assumed

$$NTU = 0.023 (0.85) (Re)^{-0.2} (4L/D_e)^{0.67} \cdot^{-1/3}$$

and assuming that $Re_g = 3000$ and $Re_a = 10,000$

$$(L/D_e)_g = (3.98) (3000)^{0.2} (0.76) / [(0.023) (0.85) (4)] = 193$$

$$(D_e)_g = 3.0/193 = 0.0155 \text{ ft} = 0.186 \text{ in.}$$

$$(L/D_e)_a = (5.52) (10,000)^{0.2} (0.76) / [(0.023) (0.85) (4)] = 343$$

$$(D_e)_a = 7.0/343 = 0.0204 \text{ ft} = 0.245 \text{ in.}$$

With these calculated values of equivalent diameter, the assumed Reynolds numbers can be checked and corrections made if there are significant differences. Calculation of passage heights and fin spacings follow customary procedure. After allowances are made for such factors as actual fin efficiencies, area occupied by metal walls, entrance and exit effects, according to the method suggested by London and Kays (2), the final predicted performance values given in Table 1 are obtained.

DESIGN OF TUBULAR REGENERATORS

From the standpoint of maximum performance for a given volume of heat-exchanger core, the use of bare tubes results in lower thermal efficiency than possible with extended-surface plate-fin construction. The foregoing analysis of extended-surface design showed that if there were no limit on the amount of surface and if the fins and separating plates could be made comparatively thin, the over-all NTU obtainable in a given volume is directly proportional to pressure-drop ratio. A similar proportion exists for tubular design but the NTU compared to extended surface is lower for the same allowable pressure-drop ratio.

The use of tubular design is often indicated on the basis of lower cost, better mechanical design, and suitability for high-pressure as well as high-temperature service. A full discussion of this subject is not within the scope of this paper.

In connection with the design of radiators and intercoolers for aircraft service, a type of heat exchanger comparable to a regenerator, a number of design charts, and methods of preparation of such charts for selecting the proper size of core have been developed (8), (9), (10), (11), (12), and (13). The procedures given usually refer to the selection of a core which has already been designed having a fixed pattern of tube spacing and diameters, or plate and fin arrangements. Tubular regenerators, on the other hand, will usually be designed for a particular model of gas turbine, so that there is a choice of both tube diameters and tube spacings. The tube length and the other dimensions will in many cases be fixed by the over-all turbine design.

^a The total surface for the tubular design is given as the sum of the outside surface and the inside surface in order to give a true comparison with the total surface of the extended surface units.

^b The over-all heat-transfer coefficient U for the extended-surface design is based on one half the total direct surface to put it on a basis comparable with the tubular design.

^c For the tubular design the coefficient U is based on the outside tube-surface area.

A General Design Relationships.

The design of tubular regenerators to some extent can follow the procedure given for the extended-surface type. The ratios of NTU's for optimum performance can be expressed by a design parameter F , but it should be noted that this parameter, given in Equation [46], is independent of the over-all dimensions of the regenerator. The relationships for a tubular design are

$$F = \frac{NTU_o}{NTU_i} = \frac{h_o A_o / C_o}{h_i A_i / C_i} \quad [46]$$

For gas-turbine regenerator one may consider that

$$C_o = C_i$$

For a bare-tube design

$$A_o/A_i = D_o/D_i$$

so that Equation [46] becomes

$$F = \frac{NTU_o}{NTU_i} = \frac{h_o D_o}{h_i D_i} \quad [47]$$

The ratio of the two heat-transfer coefficients (h_o/h_i) is obtained from the ratio of the mass velocities on the two sides which will give the highest over-all conductance U for the minimum total friction power. This ratio of mass velocities when applied to the expressions for heat transfer and incorporated in Equation [47] gives

$$F = \frac{C_s}{(D_o G_o \mu_o)^{0.17}} \left[\left(\frac{D_o}{D_i} \right) \left(\frac{v_i}{v_o} \right) \right]^{0.444} \left(\frac{T_o}{T_i} \right)^{0.272} \left(\frac{\mu_o}{\mu_i} \right)^{0.111} \quad [48]$$

The constant C_s , which is a function of tube configurations, is shown in Figs. 13 and 14. Employing this ratio of the two NTU's, one can calculate the absolute values of the individual NTU's for

FIG. 4 CONSTANT C_2 AS A FUNCTION OF TUBE SPACING; FLOW OF AIR ACROSS IN-LINE TUBES. CHART FROM (8)

FIG. 5 CONSTANT C_2 AS A FUNCTION OF TUBE SPACING; FLOW OF AIR ACROSS STAGGERED TUBES. CHART FROM (8)

a given value of over-all NTU. From the NTU_i the L/D_i of the tube is obtained by using Equation [45a]

$$NTU_i = \frac{0.023 (4L_T/D_i)}{(Re_i)^{0.4} (Pr)^{1/4}} \quad [45a]$$

The pressure drop for flow inside the tube is given by Equation [9a]

$$(\Delta P/P)_i = f \frac{V^2}{2g} \frac{4L_T/D_i}{RT_i} \quad [9a]$$

Equation [45a] may often give a tube diameter smaller than considered practical. One can redesign the unit for multipass on the tube side so that the effective tube length is increased, or accept a design which will not give the maximum NTU/(\(\Delta P/P\)) ratio for the given volume. In the latter case more surface is required for the same NTU.

The tube spacings required for the optimum ratios of heat-transfer coefficients are given by

$$(S_L/D_o) (S_T/D_o - 1) = \frac{100 (C_2/F)^{1.25} (D_i/D_o) (L_n/L_T) (\mu_o/\mu_i)^{0.25}}{(D_o G_o/\mu_o)^{0.25}} \quad [49]$$

for the case of in-line tube arrangements and staggered tube arrangements having the minimum opening in the transverse spacings. While Equation [49] does not give the absolute values of

the spacings, one can be guided by the general principle that S_T/D_o should be made as small as mechanical design limitations permit because this results in the highest heat transfer for a given friction power as indicated roughly by the plots of Figs. 6, 7, and 8 where C_2 is related to the factor $j/(f/2)$ by

$$j/(f/2) = C_2/(D_o G/\mu)^{0.27} \quad [50]$$

and C_2 is

$$C_2 = \frac{1.10 C_3}{2C_4 (S_T/D_o - 1)} \quad [51]$$

FIG. 6 CONSTANT C_4 AS A FUNCTION OF TUBE SPACING; FLOW OF AIR ACROSS IN-LINE TUBES. CHART FROM (8)

FIG. 7 CONSTANT C_4 AS A FUNCTION OF TUBE SPACING. FLOW OF AIR ACROSS STAGGERED TUBES. CHART FROM (8)

Often tube spacings will be limited by minimum ligament requirements in the tube sheet. (In the design of the regenerator for locomotive service shown in Fig. 17, close tube spacings were obtained by bending the tubes into an arc.)

The values of C_2 and C_4 are functions of Reynolds number and tube arrangement. Wood and Brevoort (8) have prepared simplified correlations, Figs. 4, 5, 6, and 7 of the data of Pierson and Huge as correlated by Grimson (14), for heat transfer and friction factors for flow across tubes. The values of the several authors are related as follows:

$C_2 = 0.31 F_a$ where F_a is the arrangement factor of Grimson and C_2 , the constant given by Wood and Brevoort in

$$hD/k = C_2 \text{Re}^{0.5} \quad [52]$$

FIG. 8 CONSTANT C_3 AS A FUNCTION OF TUBE SPACING; FLOW OF AIR ACROSS IN-LINE TUBES

FIG. 9 CONSTANT C_3 AS A FUNCTION OF TUBE SPACING; FLOW OF AIR ACROSS STAGGERED TUBES

In the preparation of their plots Wood and Brevoort incorporated the value of Prandtl number in the constant C_2 . In order to cover a wider range of gas properties the Prandtl number is reintroduced, and in-line with the treatment followed earlier in the paper, the heat-transfer expression is transformed into the Stanton number thus

$$h/c_p G = 1.10 C_2 \text{Pr}^{-1/3} \text{Re}^{-0.4} \quad [52a]$$

The pressure drop on the outside of tubes is given by

$$(\Delta P/P)_o = \frac{4f_o NG^2 v}{2gP} = \frac{4f_o NV^2}{2gPv} = \frac{4f_o N}{RT} \frac{V^2}{2g} \quad [53]$$

where

$$f_o = C_4/(\text{Re})^{0.13} = f_{\text{Grimson}} \quad [54]$$

The value of NTU_o can be obtained from Equation [52a] by incorporating the ratio of surface to net free area

FIG. 10 VALUES OF $j/(f/2)$ FOR FLOW ACROSS TUBES FOR VARIOUS VALUES OF C_s AND OF REYNOLDS NUMBER

FIG. 11 CONSTANT C_1 AS A FUNCTION OF TUBE SPACING; FLOW OF AIR ACROSS IN-LINE TUBES

$$NTU_o = \frac{1.10 C_s N}{(Pr)^{1/4} (S_T/D_o - 1) (Re)^{0.4}} \dots [55]$$

The equations here presented are sufficient for the design of a tubular regenerator which will make the most effective use of the surface employed.

B Derivation of Relationship for Optimum Performance.

The analysis of tubular design for optimum performance is predicated on the thesis that the ratio of the mass velocities on the two sides is the primary variable. The effect of tube configuration on the optimum ratio of mass velocities is treated as a second-order effect.

The several design equations must be arranged to express the variation of total friction power loss and of total resistance to

heat flow with the ratio of G_o to G_i . The following are taken as equalities

$$W_o = W_i$$

$$(c_p)_o = (c_p)_i$$

The analysis will be based on the performance of a single tube in a tube bank and the length of tube to be considered will be taken as equal to the outside diameter. This does not affect the validity of the analysis since the regenerator is merely a multiple of such an elemental area with all factors in proportion.

The performance on the inside of the tube will be considered only for the case of turbulent flow for which

$$f = 0.046/Re^{0.2}$$

and

$$j = 0.023/Re^{0.2}$$

The pressure-drop ratio is then expressed as

$$(\Delta P/P)_i = \frac{0.046}{(D_i G_i / \mu_i)^{0.2}} \frac{G_i^2 v_i^2 4(D_o/D_i)}{2gRT_i} \dots [56]$$

The amount of fluid flowing is $W = GS = G(\pi/4) D_i^2$ which, substituted in Equation [56], gives

$$(\Delta P/P)_i W_i = \left[\frac{0.046 (\mu_i)^{0.2} \pi (D_o)^{1.5} v_i^{2.2}}{2g(D_o/D_i)^{0.5} RT_i} \right] G_i^{2.2} \dots [57]$$

To simplify the handling of the equations the terms inside the brackets can be called K_i

$$K_i = \frac{0.046 (\mu_i)^{0.2} (D_o)^{1.5} v_i^{2.2}}{2g(D_o/D_i)^{0.5} RT_i} \dots [58]$$

$$(\Delta P/P)_i W_i = K_i G_i^{2.2} \dots [59]$$

FIG. 12 CONSTANT C_1 AS A FUNCTION OF TUBE SPACING; FLOW OF AIR ACROSS STAGGERED TUBES

FIG. 13 CONSTANT C_8 AS A FUNCTION OF TUBE SPACING; FLOW OF AIR ACROSS IN-LINE TUBES

The heat transfer on the inside of the tube is given by Equation [45] which becomes

$$h_i A_i = \left[\frac{0.023 (\mu_i)^{0.2} D_o^{1.8} \pi (c_p)_i}{Pr^{1/3} (D_o/D_i)^{0.8}} \right] G_i^{0.8} \dots [60]$$

Let

$$H_i = \left[\frac{0.023 (\mu_i)^{0.2} D_o^{1.8} \pi (c_p)_i}{Pr^{1/3} (D_o/D_i)^{0.8}} \right] \dots [61]$$

$$h_i A_i = H_i G_i^{0.8} \dots [62]$$

For the fluid on the outside of the tube a similar rearrangement is carried through. From Equation [53]

$$(\Delta P/P)_o = 4f_o \frac{G_o^2 v_o^2}{2g RT_o} = \frac{4C_8}{(D_o G_o/\mu_o)^{0.13}} \frac{G_o^2 v_o^2}{2g RT_o} \dots [63]$$

Instead of a friction factor f_o based on the number of tubes, N , in the direction of gas flow, one can express pressure loss by a drag factor ϕ based on the ratio of surface area to net open area

$$A/S = [\pi D_o / (S_T - D_o)] = \pi / (S_T/D_o - 1)$$

$$(\Delta P/P)_o = \phi \frac{G_o^2 v_o^2}{2g RT_o} (A/S)$$

$$= \frac{C_8}{(D_o G_o/\mu_o)^{0.13}} \frac{G_o^2 v_o^2}{2g RT_o} \frac{\pi}{(S_T/D_o - 1)} \dots [64]$$

so that

$$C_8 = \frac{C_8 (S_T/D_o - 1)}{\pi/4} \quad (\text{values for } C_8 \text{ are given in Figs. 15 and 16})$$

Multiplying both sides of Equation [64] by $W = GS$

$$(\Delta P/P)_o W_o = \left[\frac{C_8}{(D_o G_o/\mu_o)^{0.13}} \right] \left(\frac{G_o^2}{2g} \right) \left(\frac{v_o^2}{RT_o} \right) (A_o) \dots [65]$$

FIG. 14 CONSTANT C_8 AS A FUNCTION OF TUBE SPACING; FLOW OF AIR ACROSS STAGGERED TUBES

FIG. 15 CONSTANT C_8 AS A FUNCTION OF TUBE SPACING; FLOW OF AIR ACROSS IN-LINE TUBES

which simplifies to

$$(\Delta P/P)_o W_o = \frac{C_8 \pi (\mu_o)^{0.13} D_o^{1.87} v_o^2}{2g RT_o} G_o^{3.87} \dots [66a]$$

Let

$$K_o = \left[\frac{C_8 \pi (\mu_o)^{0.13} D_o^{1.87} v_o^2}{2g RT_o} \right] \dots [67]$$

FIG. 16 CONSTANT C_g AS A FUNCTION OF TUBE SPACING; FLOW OF AIR ACROSS STAGGERED TUBES

then

$$(\Delta P/P_o)W_o = K_o G_o^{2.87} \dots \dots \dots [68]$$

The heat-transfer equation is obtained from Equation [52]

$$h_o A_o = \frac{1.10 C_2 (c_p)_o G_o}{Pr^{1/3} Re^{0.4}} A_o \dots \dots \dots [69]$$

$$= \left[\frac{1.10 C_2 (c_p)_o D_o^{1.6} (\mu_o)^{0.4}}{Pr^{1/3}} \right] G_o^{0.6}$$

Let

$$H_o = \frac{1.10 C_2 (c_p)_o D_o^{1.6} (\mu_o)^{0.4}}{Pr^{1/3}} \dots \dots \dots [70]$$

then

$$h_o A_o = H_o G_o^{0.6} \dots \dots \dots [71]$$

This completes the establishment of equations to represent performance on each side of the heat exchanger. The over-all performance is given by

$$\frac{1}{UA} = \frac{1}{h_i A_i} + \frac{1}{h_o A_o} = R \text{ (resistance)} \dots \dots \dots [72]$$

Substituting Equations [62] and [71] in Equation [72] and rearranging

$$R = \frac{1}{H_i G_i^{0.8}} + \frac{1}{H_o G_o^{0.6}} \dots \dots \dots [73]$$

or

$$\frac{1}{H_o G_o^{0.6}} = R - \frac{1}{H_i G_i^{0.8}} \dots \dots \dots [74]$$

FIG. 17 TUBULAR REGENERATOR ON LOCOMOTIVE GAS TURBINE

solving for G_o gives

$$G_o = \left[\frac{1}{(H_o)(R-1)/H_i G_i^{0.8}} \right]^{1/0.6} \quad [75]$$

The total friction power loss is given by

$$(\Delta P/P)W = (\Delta P/P)_i W_i + (\Delta P/P)_o W_o \quad [76]$$

Substituting the values of the individual friction power losses from Equations [59] and [68] in Equation [76] gives

$$(\Delta P/P)W = K_i G_i^{2.8} + K_o G_o^{2.57} \quad [77]$$

Substituting the value of G_o from Equation [75] in Equation [77] gives

$$(\Delta P/P)W = K_i G_i^{2.8} + \frac{K_o}{[(H_o)(R-1)/H_i G_i^{0.8}]^{2.57/0.6}} \quad [78]$$

The optimum arrangement to obtain a given over-all heat transfer coefficient UA occurs when $(\Delta P/P)W$ is a minimum

$$\left[\frac{\partial (\Delta P/P)W}{\partial G} \right]_{UA} = 2.8 K_i G_i^{1.8} + \frac{K_o (-2.87/0.6) (0.8/H_i)}{H_o^{2.57/0.6} (R-1/H_i G_i^{0.8})^{2.57/0.6} (G_i)^{1.8}} \quad [79]$$

Setting this derivative equal to zero will give the minimum for

$$\begin{aligned} 0 &= 2.8 K_i G_i^{1.8} - \left(\frac{2.87}{0.6} \right) \frac{(K_o)(0.8)}{H_i [H_o^{2.57/0.6} (R-1/H_i G_i^{0.8})^{2.57/0.6} (G_i)^{1.8}]} \\ 0 &= 2.8 K_i G_i^{1.8} - \frac{(2.87)(0.8)}{(0.6)} \left(\frac{K_o H_o}{H_i} \right) G_i^{2.57} \\ \frac{G_i^{2.6}}{G_o^{2.57}} &= \frac{(2.87)(0.8)}{(2.8)(0.6)} \frac{K_o H_o}{K_i H_i} = 1.37 \frac{K_o H_o}{K_i H_i} \quad [79] \end{aligned}$$

Substituting the values of $K_o H_o / K_i H_i$ in Equation [79] and simplifying, results in the ratio of G values for optimum performance

$$\frac{G_i}{G_o} = \frac{1}{(D_o G_o / \mu_o)^{0.087}} \left\{ \frac{[(1.10)(C_2)(C_3)(1.37)]}{(0.046)(0.023)} \left(\frac{\mu_o}{\mu_i} \right)^{0.4} \left(\frac{D_o}{D_i} \right)^{1.0} \left(\frac{v_o}{v_i} \right)^2 \left(\frac{T_i}{T_o} \right)^{0.273} \right\} \quad [80]$$

Let $C_7 = \left[\frac{1.37(1.10)(C_2)(C_3)}{(0.046)(0.023)} \right]^{0.273}$ (the values of C_7 are given in Figs. 11 and 12)

$$\frac{G_i}{G_o} = \frac{C_7}{(D_o G_o / \mu_o)^{0.087}} \left(\frac{\mu_o}{\mu_i} \right)^{0.11} \left(\frac{D_o}{D_i} \right)^{0.444} \left(\frac{v_o}{v_i} \right)^{0.555} \left(\frac{T_i}{T_o} \right)^{0.273} \quad [81]$$

This ratio of mass velocities is seen to be largely a function of the ratio of specific volumes. The value of the constant C_7 changes only slightly with tube configuration. Reynolds number on the outside of the tubes comes in only to a low power. The viscosity, temperature, and diameter ratios have only a small effect. This optimum ratio can be used to arrive at the design parameter F given in Equation [48] or it can be used in any other design procedure to arrive at final performance values.

These equations have been used for designing a tubular regenerator for the same conditions as given previously for the extended-surface type. Predicted performance values are given in Table 1 for two alternate tubular designs. In one design the effectiveness is kept the same as for the extended surface. The much higher pressure drop for tubular design is strikingly apparent. In the other design the pressure drop is kept approximately the same as for the extended-surface type and as a result the effectiveness is considerably reduced. Offsetting this poorer thermal performance is the much smaller amount of actual metal-surface area employed in the tubular design.

Comparisons under other conditions can readily be made by means of the equations presented here.

ACKNOWLEDGMENTS

The author wishes to express his indebtedness to Mr. L. C. Claiborne who developed the relationships for optimum performance of tubular regenerators, and to the Elliott Company who supported this study and agreed to publication of the analysis.

Correlation of Plastic Deformation During Metal Cutting With Tensile Properties of the Work Material

By J. T. LAPSLEY, JR.,¹ R. G. GRASSI,² AND E. G. THOMSEN,³ BERKELEY, CALIF.

An experimental correlation of plastic deformation occurring during metal cutting with the plastic deformation in tension of the work material; an analysis permitting comparison of these two states of strain is presented. Orthogonal cutting of seamless steel tubing was employed for feeds of 0.0025–0.0085 in. per revolution (ipr), and positive rake angles of 25–45 deg. Deformation and forces of cutting were obtained from chip measurement and from a tool dynamometer employing resistance strain gages. The agreement obtained indicates that the tensile properties of the work material may offer a useful index to metal-cutting performance.

NOMENCLATURE

The following nomenclature is used in the paper:

F_T = thrust force, lb; measured in direction of motion of tool by tool dynamometer in orthogonal cutting

F_C = cutting force, lb; measured perpendicular to direction of motion of tool by tool dynamometer in orthogonal cutting

l, l_o = final and original length, respectively, in.; refers to chip length in metal cutting and gage length in tension testing

D_o, D = original and instantaneous diameter, respectively, of neck in a tension bar, in.

α = rake angle, deg; measured in plane perpendicular to cutting edge

ϕ = shear angle, deg; angle between shear plane and surface being generated, measured in plane perpendicular to cutting edge

A_s = area of shear plane, sq in.

τ_{ss} = mean shear stress on shear plane (in metal cutting) psi

γ_{ss} = shearing strain of chip during removal in metal cutting

$\bar{\sigma}_x, \bar{\sigma}_y, \bar{\sigma}_z$ = normal true stresses at a point in a deformed metal, measured parallel to three co-ordinate directions x, y, z , respectively, psi

$\tau_{xy}, \tau_{yz}, \tau_{zx}$ = shearing stresses on planes perpendicular to co-

ordinate axes of first subscript, and in direction of second subscripts, psi

$\bar{\epsilon}_x, \bar{\epsilon}_y, \bar{\epsilon}_z$ = finite plastic true strains associated with the normal stresses $\bar{\sigma}_x, \bar{\sigma}_y, \bar{\sigma}_z$, respectively

$\gamma_{yz}, \gamma_{xz}, \gamma_{xy}$ = shearing strains associated with shearing stresses $\tau_{yz}, \tau_{xz}, \tau_{xy}$, respectively

Effective true stress =

$$\sqrt{\frac{(\bar{\sigma}_x - \bar{\sigma}_y)^2 + (\bar{\sigma}_y - \bar{\sigma}_z)^2 + (\bar{\sigma}_z - \bar{\sigma}_x)^2}{2} + 3(\tau_{xy}^2 + \tau_{yz}^2 + \tau_{xz}^2)}$$

(complex stress function, psi)

Effective finite plastic strain =

INTRODUCTION

Tool life, the time a tool remains serviceable under a given set of conditions, is probably the most important practical index of machinability. An appreciable amount of data is now available which can be expressed by the formula $VT^n = C$, where V is cutting velocity in feet per minute, T is tool life in minutes, n and C are constants depending on the cutting conditions, nature of work material, and other factors. While this relationship between velocity and tool life is quite general, the constants n and C hold only for specific conditions. For each new condition of metal cutting for which no information is available, time-consuming and costly experiments must be performed to find the numerical values of these constants. Consequently, a correlation of tool life with physical constants pertaining to the cutting condition, similar to the correlation of friction factor with Reynolds modulus in hydrodynamics, would be an important contribution.

In order to establish a general functional relationship of tool life with physical constants of tool work, conditions in the cutting zone, such as temperature, abrasiveness of the work at this temperature, the mechanics of metal cutting, and the state of plastic deformation of the chip must be established. It is the purpose of this paper to discuss the mechanism of metal cutting and to correlate the state of plastic deformation of metal cutting with that of the tension test.

In this investigation, orthogonal cutting of seamless steel tubing was used with values of feed from 0.0025 to 0.0085 in. per revolution (ipr) and positive back-rake angles on the cutting tool of 25 deg, 35 deg, 40 deg, and 45 deg. Cutting was done dry with a high-speed-steel tool at approximately 90 fpm.

EXPERIMENTAL TECHNIQUE

Orthogonal cutting, in which a straight-edged cutting tool moved relative to the workpiece in a direction perpendicular to its cutting edge, was employed. The cutting conditions were such as to yield continuous chip formation without a built-up edge on the tool. This type of chip formation has been designated as a type-2 chip (1).⁴

The force system for orthogonal cutting, developed by Merchant (2) is shown in Fig. 1. The resultant force R may be resolved into components, the cutting force F_C , and the thrust force

Fig. 1 FORCE SYSTEM ACTING ON CHIP DURING ORTHOGONAL CUTTING

F_T , which were measured by the tool dynamometer employed. Resolution of the force R along the shear plane, designated by the shear angle ϕ , results in F_S , the shearing force, and F_N , the force perpendicular to the shear plane. The force of friction is represented by F , and the force component perpendicular to the tool face by N . The friction angle and back-rake angle are represented by μ and α , respectively. The lack of collinearity of R and R' is not significant and has been so shown by others (2).

On the basis of Merchant's analysis, it has been shown that the work of cutting is

$$W_s = F_C/t_o w_o \dots \dots \dots [1]$$

where t_o and w_o are original chip thickness and width, respectively.

The work of shear is obtained from the relationship

$$W_s = \tau_{xz} \gamma_{xz} \text{ or } (W_s = S_s \epsilon, \text{ according to Merchant}) \dots [2]$$

where $\gamma_{xz} = \cot \phi + \tan (\phi - \alpha)$, and τ_{xz} is the shear stress on the plane designated by the angle ϕ .

The shear angle ϕ , is determined from the chip geometry by the following expression providing the chip width remains constant

$$\tan \phi = \frac{l}{l_o} \cos \alpha / \left(1 - \frac{l}{l_o} \sin \alpha \right) \dots \dots \dots [3]$$

where l_o and l are the initial and final chip lengths, respectively.

Metal cutting was done by machining the end of a short section of 6-in.-OD, 0.475-in wall thickness, seamless steel tubing. The tubing was in the "as-received" or unannealed condition. The cutting tool, of high-speed steel, was clamped in a special holder mounted on the compound rest of an engine lathe. The tool was set on center and fed perpendicularly to the end of the tube which was clamped in a four-jaw chuck. Cutting was done dry, at 57 rpm, or approximately 90 fpm. This cutting speed was selected to obtain a moderate strain rate in the chip.

⁴ Numbers in parentheses refer to the Bibliography at the end of the paper.

The tool dynamometer had as its measuring elements SR4 type A-5 electrical strain gages. The gages were mounted as shown in Fig. 2, with two active gages in adjacent legs of a conventional bridge circuit for each force determination. This arrangement increased sensitivity and also provided a means of eliminating temperature effects. Coolant was circulated through

Fig. 2 SCHEMATIC DRAWING OF TOOL DYNAMOMETER USED IN MEASURING ORTHOGONAL CUTTING-FORCE COMPONENTS, F_C AND F_T

the tool shank so that heat generated during cutting did not produce a temperature differential between the strain gages. The stability of the gages was maintained by protection with wax, Ozite, and a metal shield.

The calibration of the dynamometer utilized a 5000-lb proving ring. The calibration for the thrust force F_T , was accomplished with the tool clamped in the holder used for cutting and mounted on the compound rest. Force was uniformly applied to the cutting edge through the proving ring by means of special adapters and manual carriage motion. The dynamometer calibration for the cutting force F_C , was performed with the tool mounted in its holder and clamped to the table of an upright drill press. The force was applied uniformly to the cutting edge (similar to F_T), by using manual spindle travel.

The dynamometer was designed so that the measurement of one force was independent of the other. The calibrations proved that this design criterion had been achieved. Simultaneous recording of F_T and F_C was obtained by using strain recorders. The time of cutting varied with conditions and was dependent upon attaining equilibrium values of forces and a representative number of chips. Since the chip width remained constant, the relationships previously presented are applicable. The initial conditions of chip thickness, and length, l_o and l_s , were determined from the feed and outside diameter of the tube, respectively. A reference point for measuring the final chip length, l_s , was established by cutting a shallow longitudinal slot in the outside surface of the tube. This measurement was facilitated by the fact that the chips did not curl during removal.

Specimens for the tension test were cut from the tube wall so that their axes coincided with that of the tube. The gage section was 1 1/4 in. long and 0.250 in. diam.

EXPERIMENTAL RESULTS

The experimental data of the metal-cutting tests are presented in Table 1 and are shown graphically in Figs. 3 to 6, inclusive. Although these data are not the primary objective of this investigation, they show some interesting trends which also establish their consistency.

Figs. 3 and 4 indicate the effect of back rake and feed, respectively, on the tool forces. It may be noted that the change in

feed results in a greater change in the cutting force than in the thrust force. Figs. 5 and 6 show the amount of work expended per unit volume of metal removed in cutting and in shear deformation, respectively. Examination of these figures indicates that the work expended for rake angles 45 deg, 40 deg, and 35 deg is appreciably lower than that expended for the 25-deg back-rake angle. This behavior might be attributable to the presence of a nonobserved built-up edge.

DISCUSSION

The metal of the chip during metal cutting is severely deformed and, therefore, is in a highly work-hardened state. It is possible to compare this state of work-hardening with that obtained by any other deformation process by application of a theory of plasticity (3, 4), providing the states are calculable and the metal under consideration satisfies the assumptions made in the ideal theory. The assumptions are as follows:

- (a) The metal is isotropic.
- (b) The metal is homogeneous.
- (c) The stresses are linear functions of the infinitesimal plastic strains.
- (d) Temperature, deformation rate, and hydrostatic pressure do not affect the state of plastic deformation.

While real metals do not behave ideally, it has been shown (5) that low-strength aluminum alloys, magnesium alloys, and mild steel satisfy the foregoing assumptions to a good degree of approximation when equivalent states of work-hardening in tension, compression, and torsion are compared. The following section will be devoted to the development necessary for correlation between the plastic state in a chip and in a tension bar by application of this theory of plasticity.

If the previously stated assumptions are satisfied, it can be shown that equivalent states of work-hardening can be represented on an effective stress-effective plastic strain curve. Two complex stress and strain functions utilized in the correlation are

$$\sqrt{\frac{(\bar{\sigma}_x - \bar{\sigma}_y)^2 + (\bar{\sigma}_y - \bar{\sigma}_z)^2 + (\bar{\sigma}_z - \bar{\sigma}_x)^2}{2} + 3(\tau_{xy}^2 + \tau_{yz}^2 + \tau_{xz}^2)} \dots [4]$$

Effective plastic strain =

$$\frac{2}{3} \sqrt{\frac{(\bar{\epsilon}_x - \bar{\epsilon}_y)^2 + (\bar{\epsilon}_y - \bar{\epsilon}_z)^2 + (\bar{\epsilon}_z - \bar{\epsilon}_x)^2}{2} + \frac{3}{4}(\gamma_{xy}^2 + \gamma_{yz}^2 + \gamma_{xz}^2)} \dots [5]$$

The work of plastic deformation for any particular state of deformation is given by the area under the curve from zero strain to the value under consideration.

While the stress or strain path employed does not affect the validity of the universality of the effective stress-effective plastic strain curve, it is only possible to determine the plastic state in a few simple cases. The infinitesimal plastic strains, from which the finite strains under the radical of the effective strain are constructed, are not perfect differentials. The finite strains are, therefore, path dependent and can be obtained by integration only if the stress or strain path is known. In the present investigation it is assumed that the stress ratios remain constant during the entire deformation, thus permitting the evaluation of the finite strains in terms of quantities measurable before and after the deformation. With this additional assumption, it is possible to calculate the plastic states for tension and metal cutting.

The Tension Test. Let the x -co-ordinate axis be coincident with the axis of the test bar. Therefore, $\bar{\sigma}_x$ is the true stress resulting from the applied axial load

$$\bar{\sigma}_x = \frac{\text{Axial load}}{\text{Instantaneous area}} \dots [6]$$

Since $\bar{\sigma}_x$ is the only stress, the effective stress reduces to

$$\text{Effective stress (in tension)} = \bar{\sigma}_x \dots [7]$$

The finite plastic strain $\bar{\epsilon}_x$ in the axial direction can be determined from measurements of the original gage length and the length at any stage of the deformation up to the maximum load

$$\bar{\epsilon}_x = \log_e \frac{l}{l_0} \dots [8]$$

where l_0 and l are initial and final gage length, respectively.

After the maximum load has been exceeded, the specimen necks and the deformation ceases to be uniform over the gage length. The axial strain, however, can be obtained from measurements of the minimum diameter in the neck for constant volume deformation

$$\bar{\epsilon}_x = 2 \log_e \frac{D_0}{D} \dots [9]$$

where D_0 and D are initial and instantaneous diameter, respectively, at any stage of deformation.

By use of the constant-volume relationship, the effective plastic strain can be evaluated in terms of the normal strains

$$\bar{\epsilon}_x + \bar{\epsilon}_y + \bar{\epsilon}_z = 0 \dots [10]$$

but

$$\bar{\epsilon}_y = \bar{\epsilon}_z$$

therefore

$$-\bar{\epsilon}_y = -\bar{\epsilon}_z = \frac{1}{2} \bar{\epsilon}_x \dots [11]$$

Substituting these values of strain into Equation [5] results in

$$\text{Effective plastic strain (tension)} = \bar{\epsilon}_x \dots [12]$$

Consequently, the effective stress-effective plastic strain curve

is identical with the true stress-true plastic strain curve in tension.

When necking occurs, the stress ceases to be uniform as has been shown by Bridgman (6). In general, however, the error introduced by assuming a constant stress across the section is not significant.

Metal Cutting. Merchant (7) has shown that it is possible to obtain an analysis of the metal-cutting process by assuming that the deformation is simple shear. The shearing process is visualized to take place on a plane making an angle ϕ with the original work surface, as shown in Fig. 1. The slight curvature of the shear plane observed from photomicrographs has been neglected in the analysis. The deformation stress τ_{xy} on this plane is obtainable from the measured tool forces, while the shearing strain γ_{xy} is calculable from chip-deformation measurements

$$\tau_{xy} = \frac{F_C \sin \phi \cos \phi - F_T \sin^2 \phi}{l_0 w_0} \dots [13]$$

$$\gamma_{xy} = \cot \phi + \tan (\phi - \alpha) \dots [14]$$

where l_0 and w_0 are the initial thickness and width of chip, respectively.

ANAL

In addition to the shearing stress, a normal stress, $\bar{\sigma}_x$, acts on the shear plane

$$\bar{\sigma}_x = \frac{F_C \sin^2 \phi + F_T \sin \phi \cos \phi}{l_0 w_s} \quad [15]$$

Since the analysis is based only on the shear strain, the effective strain reduces to

$$\text{Effective strain (metal cutting)} = \frac{\sqrt{3}}{3} \gamma_{xz}; \quad \gamma_{xz} = \gamma_{zx} \quad [16]$$

However, a further assumption must be made in order to calculate the effective stress. Since τ_{xz} is the only shear stress acting, $\tau_{yz} = \tau_{zy} = 0$. Of the normal stresses, only $\bar{\sigma}_x$ is known; it is therefore necessary to assign values to $\bar{\sigma}_y$ and $\bar{\sigma}_z$. While values cannot be fixed, a priori, it is reasonable to assume that the state of stress is that of hydrostatic pressure on the shear plane. Under this condition, the three normal stresses are equal and are eliminated from the effective-stress expression, Equation [4]. The effective stress, therefore, reduces to

$$\text{Effective stress (metal cutting)} = \sqrt{3} \tau_{xz}; \quad \tau_{xz} = \tau_{zx} \quad [17]$$

Correlation Between Tension and Metal Cutting. Fig. 7 shows the calculated metal-cutting data and the stress-strain curve obtained from tension tests for the same material. The solid line represents the experimental data from tension tests which were extrapolated to higher values of strains than those achievable in tension, as shown by the dashed portion of the curve. Such extrapolation is not unreasonable; for example, higher strains may be obtained in torsion. It is evident that there is good agreement between the tension data and the metal-cutting data.

The fact that the effective stress values for a given rake-angle group about a particular strain value indicates that factors not taken into account are active. Merchant (7) proposes that the normal stress on the shear plane (a condition of hydrostatic pressure in the present analysis) influences the shear stress. While this may be an important factor, it is not clearly proved to be the only factor, as the experimental data, reported by Merchant, show scatter when the normal stress is considered. Further investigation is necessary to establish which assumptions are not valid and what other variables must be considered.

Fig. 8 shows a comparison of the work of deformation per unit volume of metal removed as calculated from the shear work of metal cutting and from the tension test. The deformation work based upon tension was obtained by evaluating areas under the

FIG. 7 CORRELATION BETWEEN EFFECTIVE STRESS-EFFECTIVE PLASTIC STRAIN VALUES AS CALCULATED FROM (1) PLASTICITY ANALYSIS OF METAL-CUTTING DEFORMATION; (2) TENSION TEST OF WORK MATERIAL

FIG. 8 WORK OF DEFORMATION AS FUNCTION OF SHEAR STRAIN, γ_{xz} , FOR (1) SHEAR STRESS-SHEAR STRAIN ANALYSIS OF METAL CUTTING AS DEVELOPED BY MERCHANT; (2) EFFECTIVE STRESS-EFFECTIVE PLASTIC STRAIN ANALYSIS BASED ON TENSION-TEST DATA

effective stress-effective plastic strain curve, presented in Fig. 7. An empirical equation was determined for this curve

$$\text{Effective stress} = 110 \times 10^3 (\text{effective plastic strain})^{0.102} \quad [18]$$

Work of deformation for given shear-strain values was determined by integration of the equation between limits of zero strain and the corresponding effective plastic-strain value.

From the comparison it is seen that the work of deformation, as determined from the metal-cutting analysis, exceeds the deformation work based upon the tension test for all cutting conditions employed in this investigation. It is felt that the present information is insufficient for an adequate explanation of this anomaly and that further investigation should be made.

CONCLUSIONS

- 1 The results of the investigation have shown that metal-cutting data can be correlated with tension data for orthogonal cutting and the test conditions employed.
- 2 The tension properties of a material may offer a useful index of cutting performance.
- 3 The work done by shear deformation, calculated from metal-cutting data, results in larger values than that determined from the tension test for equivalent states of deformation.
- 4 Further application of the plasticity theory should yield information which could give a more basic understanding of metal cutting.

Discussion

M. EUGENE MERCHANT.⁶ The authors have contributed some much-needed information by carrying out cutting tests and tensile tests on the same material, and then comparing the mechanical properties of the material as calculated from the data obtained on the two types of tests. They are to be congratulated on the manner in which they have carried through the test work and analysis; such information serves to clarify further the fundamentals of the cutting process and their relation to the mechanical properties of the metal being machined.

The mathematical analysis which the authors have used to compare the metal-cutting results with those from the tensile tests provides good correlation between the two sets of data. However, this mathematical analysis is based on certain assumptions which are questionable when applied to the metal-cutting process. Therefore it appears somewhat fortuitous that such good agreement was obtained. In particular, the main basis for the mathematical theory used to compare the two sets of data is that states of work-hardening occur in the plastic deformation taking place on the shear plane in metal-cutting which are equivalent to those obtained in a normal tensile test. The fallacy here is brought out by Drucker,⁷ who points out that in the process of metal cutting virtually no work-hardening of the metal occurs on the shear plane because of the extremely high strain rates involved in the cutting process. (The "work-hardening" actually observed in hardness measurements on chips virtually all occurs after deformation on the shear plane is complete, since work-hardening is a "rate-process," like a chemical reaction!)

In the tensile test, of course, work-hardening does occur, since the rate of strain is quite low. Further, the very fact that an extremely high strain rate is involved in the cutting process, compared to the very low strain rates involved in tensile tests, will have a marked effect on the actual shear strength of the metal in the two cases; shear strength is known to increase with increasing strain rate. Therefore, in the two types of deformation in actuality there can be no comparable states of work-hardening, and so the basic premise of the authors' theory is not met.

Nevertheless, it appears from the test results reported by the authors (as well as from data obtained in the writer's laboratory, as will be shown shortly) that reasonable agreement can be obtained between mechanical properties observed from cutting tests and those observed from low-strain-rate tests. The reason for this fortunate result is not immediately evident; it appears, however, that the complicating factors involved tend to balance each other. Presumably, the "weakening" effects of the absence of work-hardening and the local heating on the shear plane in cutting offset the "strengthening" effect of the very high strain rate reasonably well. The net result apparently makes the stress values obtained from the two types of tests very nearly equal, for the range of strains and strain rates usually found in machining.

Another factor which the authors have (admittedly) neglected in making the comparison between the tensile-test data and those from metal-cutting is the effect of compressive stress (or hydrostatic pressure) on the actual values of shear strength calculated from metal-cutting data.

As pointed out previously by the writer,⁷ the shear strength of the metal on the shear plane in metal cutting is raised by the presence of a high value of compressive stress acting on that

plane. No such compressive stress acts on the slip processes occurring in the tensile tests. (In fact, the reverse is true.) Therefore the values of shear strength calculated from the authors' metal-cutting data ought, in all fairness, to be corrected to a value of zero compressive stress (at least), if they are to be compared with strength values from the tensile tests. This can be done, approximately, for the data presented by the authors, by extrapolating the shear-strength versus compressive-stress data back to zero compressive stress, making use of metal-cutting theory. When this is done, it is found that the calculated shear strength (τ_{ss}) for the steel used by the authors is approximately 60,000 psi (this value is independent of strain since no work-hardening occurs in the metal-cutting process, as previously mentioned). Thus the effective stress value ($\sqrt{3}\tau_{ss}$) is approximately 100,000 psi. This value is still in reasonable agreement with the authors' tensile-test data.

Actually, to be wholly fair, the tensile-test data ought also to be corrected to a value of zero hydrostatic pressure, which would increase the effective stress values somewhat. No effort has been made to do this, however, since the effect probably would be slight, and no provision for such correction has been made in the theory of plastic deformation used by the authors in analyzing the tensile tests.

Comparisons between metal-cutting data and data obtained from low strain-rate tests of mechanical properties, somewhat similar to the comparison reported by the authors, have been carried out in the writer's laboratory^{8,9} recently. However, these low-strain-rate tests were made by quite a different method from the tensile tests employed by the authors; a method developed by Bridgman¹⁰ was used wherein notched tubular specimens are tested in torsion while subjected to an axial compressive force. Here again, surprisingly good correlation between the metal-cutting data and those obtained from this torsion-compression type of test was obtained, even though the strain rates and corresponding work-hardening states were very different. A comparison of the values of shear strength calculated from the two types of tests at comparable values of compressive stress and shearing strain are given in Table 2 of this discussion. It may be seen that the shear-strength values calculated from the two types of tests agree surprisingly well, considering the great dif-

TABLE 2 COMPARISON OF SHEAR-STRENGTH VALUES OBSERVED FROM TORSION-COMPRESSION-TYPE TESTS WITH THOSE OBSERVED FROM METAL-CUTTING TESTS, AT EQUIVALENT VALUES OF COMPRESSIVE STRESS

ferences that exist between the conditions of deformation in the two cases.

In metal cutting three mechanical properties of the material being machined control the forces acting on the cutting tool.⁷ These are as follows:

- 1 Shear strength of the material.
- 2 Machining constant of the material (a property of the material, the value of which, in theory, depends upon the rate of increase of shear strength with applied compressive stress).

3 The coefficient of friction between the cutting tool and the flowing chip.

Of these three quantities needed to predict cutting forces in machining, only the first can be obtained from a tensile test by the methods used by the authors. The torsion-compression type of test mentioned has the advantage not only of giving values of shear strength, but also of providing theoretical values of machining constant; the increase in (torsional) shear strength as increasing axial compressive force is applied to the tubular test specimen can be observed in this type of test. Again, reasonably good correlation with metal-cutting data is obtained, as shown by the values of machining constant given in Table 3 herewith. Here the agreement is not as good as for the shear strength values (Table 2), but still serve well enough for a first approximation.

TABLE 3 COMPARISON OF VALUES OF MACHINING CONSTANT OBSERVED FROM TORSION-COMPRESSION TYPE TESTS WITH THOSE OBSERVED FROM METAL-CUTTING TESTS, AT EQUIVALENT VALUES OF SHEARING STRAIN

In conclusion, we again wish to congratulate the authors for their fine beginning on the exploration of fundamentals in metal cutting. It is pleasing to note from the concluding paragraph of the paper that the present work does, in truth, mark only a beginning and that we may look forward to further interesting reports in this field from the authors.

MILTON C. SHAW.¹¹ The authors have presented a most interesting discussion of the application of the distortion-energy theorem of plasticity to the cutting of metals. This idea of considering the states of stress in two bodies as equivalent when the same energy of distortion is associated with each is another of the many contributions of James Clerk Maxwell (1856).¹² The distortion-energy theorem represents the plasticity condition that has been most successful to date in relating the flow characteristics of two homogeneous bodies of different geometry and stress distribution. This method is one way of introducing the effect of strain-hardening into the theory of cutting.

The authors have listed carefully the assumptions upon which the distortion-energy theorem is based. These might be considered briefly in light of the experimental results. Despite the fact that all metals are far from homogeneous, the size or mean period of the inhomogeneity is generally very small compared with the size of the body undergoing plastic flow, and good results are obtained by treating the material as a homogeneous continuum. However, when the specimen is small, the fact that the material is actually inhomogeneous becomes more important. For example, the distortion-energy theorem indicates that all tensile-test specimens made from a given material should have the same ultimate stress regardless of diameter of the specimen. This is not the case however, for it is found that as the diameter is decreased below a particular diameter, the ultimate stress increases. This size effect is to be expected whenever strain hardening occurs in an inhomogeneous material.

¹¹ Associate Professor of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Mass. Mem. ASME.

¹² Letter by Maxwell to William Thomson dated Dec. 18, 1856, published in *Proceedings of Cambridge Philosophical Society*, Part V, vol. 32.

In the cutting process, the depth of cut corresponds to the diameter of the tensile-test specimen, and it is apparent that in cutting we are generally dealing with small specimens. It is not surprising, therefore, that the authors' test points fall above the tensile-test data for the 1/4-in.-diam specimen in Fig. 7 of the paper, and further that the cutting-data points lie an increasing distance above the tensile curve as the chip size decreases.

The writer recently has completed work on a theory of cutting which takes strain-hardening and the inhomogeneity of the metal cut into consideration. This analysis, which will be published elsewhere, is in good agreement with the authors' data and shows quantitatively that the shear work to remove a cubic inch of material increases as the depth of cut decreases, as may be seen in Table 1, Fig. 8, of the paper. It might be remarked at this point that the reason for the increase in specific shear work with rake angle (for a given depth of cut), as shown in Fig. 8, is due to the increase in the shear strain arising in the cutting process as the depth of cut is decreased.

The assumption regarding the unimportance of temperature and the rate of strain in application of the distortion-energy theorem might also be considered. The true stress-strain curve is usually obtained under essentially static conditions, while the cutting process, on the other hand, involves a very high rate of strain. From photomicrographs it is evident that nearly all of the large strain that occurs in cutting takes place as the metal crosses the "shear plane." If this were truly a mathematical plane, we would have, in the cutting process, strain at an infinite rate. Actually, we may say the rate of strain in cutting is very high.

Since nearly all of the energy associated with the plastic-straining of metals appears in the form of heat, it is evident that a significant temperature rise is to be expected in the essentially adiabatic straining process of cutting, while a relatively small temperature rise is to be expected on the shear plane in the nearly isothermal-straining process of the ordinary true stress-strain test. The temperature on the shear plane is apt to be far more significant in the cutting process than in other processes to which the distortion-energy theorem is applied. Thus it is evident that the extreme conditions of size and rate of strain that are met in the cutting process provide a serious test of the assumed independence of strain mechanism and the temperature effect in Maxwell's distortion-energy theorem.

The authors have assumed the normal stress on the shear plane to be a manifestation of the presence of a hydrostatic pressure. This leads naturally to the result that the state of stress in cutting is independent of the normal stress on the shear plane, which, however, is in disagreement with Merchant's theory of cutting. The fact that the authors' analysis is in such good agreement with experiment (except for the afore-mentioned size effect) indicates strain-hardening and not the influence of normal stress on the shear plane to be the important item. It is therefore enlightening to examine the authors' data according to Merchant's analysis.⁷

In Fig. 9, herewith, the authors' data are shown plotted with normal stress against shear stress. According to Merchant, all of these points should be along a single straight line. Therefore we might choose either of the lines shown. According to Merchant's plasticity condition, when the observed shear angle ϕ is plotted against the quantity $(\tau - \alpha)$, where τ is the friction angle, and α the rake angle, a straight line should be obtained whose equation is

$$\phi = \frac{1}{2}(\tau - \alpha) + \cot^{-1} K \dots \dots \dots [19]$$

where K is the slope of the line in Fig. 9.

The authors' data points are shown as circles in Fig. 10 of this

FIG. 9

discussion, while the two lines corresponding to those of Fig. 9 are shown solid and dotted. The dash line corresponds to a value of K of zero (i.e., the case corresponding to the authors' finding that shear strength is independent of normal stress on the shear plane). Most of the authors' data are seen to be in better agreement with the dash line corresponding to $K = 0$. Only those points corresponding to a rake angle of 25 deg are in agreement with the solid curve, and there is apparently no justification for the dotted curves in Figs. 9 and 10.

Actually, it would appear that the test points lie along or somewhat below the dash line in Fig. 10, the distance below the line increasing as the rake angle decreases. The increase in temperature on the shear plane which accompanies strain has not been included in the analysis leading to the upper line in Fig. 10, but if included would move the line vertically downward an increasing amount as the shear energy increased. This could account for the fact that points fall progressively farther below the upper line in Fig. 10, as the rake angle is increased, for as previously mentioned, the amount of strain, and hence the shear work required to remove a cubic inch of metal, also increases as the rake angle is decreased. It would thus appear that the authors' data are in full support of the view that strain-hardening is an important consideration in the metal-cutting process, and further that the influence of normal stress on the shear plane is relatively insignificant.

AUTHORS' CLOSURE

The authors are appreciative of the discussions submitted by Dr. Merchant and Professor Shaw. It is gratifying to note their interest in the paper as evidenced by the comments. However, there exist some areas of disagreement which we believe will be resolved only by further experimental investigations.

Merchant's comments hinge essentially upon two considerations, (1) absence of work-hardening effect during metal cutting as postulated by Drucker and (2) the effect of compression upon shear strength as reported by Bridgman. The large variation in strain rates is the basis for Merchant's comment that the

FIG. 10

two states of work-hardening (metal cutting and tension test) are not comparable. The authors' simplifying assumption (d) regarding strain rate should be modified if and when experimental data establish the order of importance of strain rate. However, in the absence of such experimental data, the authors cannot agree with the comment of Merchant based upon Drucker's theoretical analysis that work-hardening does not occur during metal cutting because of the relatively high strain rates involved.

The effect of normal stress on the shear strength or flow stress, referred to by Merchant, has been neglected by the authors because this effect has not been clearly demonstrated. The results of Bridgman cited in Merchant's paper (Bibliography 7) did not demonstrate clearly that the effect holds for all metals. In fact, Bridgman concludes that the shear stress at a definite strain value of unity increases with normal stress only for drill rod, but for SAE 1045 carbon steel the variation was within the order of experimental accuracy. If subsequent experimental work shows the normal stress factor to be appreciable, it can be incorporated in the plasticity analysis.

The authors agree in general with comments made by Shaw. The assumptions stated in the paper, such as homogeneity and isotropy of the work material, are simplifying assumptions only and should not be considered as hard and fast rules. Refinements can be applied to the plasticity theory, based on Maxwell's original hypothesis and restated by others in several ways, as certain effects not incorporated in this theory are isolated.

The authors have also applied Merchant's criteria for metal cutting as shown in the graphs of Figs. 9 and 10. In view of the hypothesis, however, that the effect of work-hardening in metal cutting is important, they have felt that insufficient data were available to isolate this effect, inasmuch as comparisons ought only to be made at equivalent states of work-hardening.

In conclusion, the authors wish to thank the discussers for their interest and to state that the approach presented in their paper should be regarded as a basis for further investigation. Additional experimental work, now in progress, indicates that the analysis correlates also for materials other than that reported.

Improved Nails

Their Driving Resistance, Withdrawal Resistance, and Lateral Load-Carrying Capacity

By E. GEORGE STERN,¹ BLACKSBURG, VA.

Approximately 3600 tests were performed on the driving resistance, withdrawal resistance, lateral load-carrying capacity, withdrawal, and deformation of 2, 2 $\frac{1}{2}$, 3, 3 $\frac{1}{2}$, and 4-in-long plain-shank, spirally grooved, and annularly grooved nails in southern yellow pine, white oak, and beech, in order to make available comparative test and design information on these nails. Data on nail properties, as influenced by nail type, size, point, shank pilot, steel composition, heat-treatment, cement coating, wood species, wood density, and annual rings of the wood are presented to help in determining the type of nail most suitable for specific applications. At a later date a report will be issued on the effects of change in moisture content and elapsed time after driving, on the foregoing test variables, since these factors could not be investigated until after the test planks had been air-seasoned. Such a study was made possible because all nails for tests on withdrawal resistance and lateral load-carrying capacity were driven at that time of test performance when oak and beech were green and pine was partially air-dry.

INTRODUCTION

DIRECTLY or indirectly, nails are in everyday use by almost everyone. Without being in the limelight or conspicuous, they are essential to human comfort and living, since they are of fundamental importance in most wood products. Little is known about the behavior of nails once driven into wood. Experience governs their use. If one nail does not perform the job, a second one is used. If a large nail splits a piece of wood, one or two small ones are used instead. So many people want to know how to use nails properly, but few have the opportunity to collect enough experience to have the necessary know-how. To complicate matters, the number of types and sizes of nails in production and use is great. The round, triangular and square-shank nails are made as plain-shank, barbed, coated, twisted, spirally grooved, annularly grooved, nontempered or tempered nails with low or high-carbon steel, stainless steel, aluminum, copper, brass, bronze, silicon bronze, or other alloys; with short, medium, and long diamond, needle, chisel, duck-bill, side or V-points; with standard, medium or large flat, countersunk, round, oval, brad or duplex heads. They are merchandised as common nails, finishing nails, fiberboard nails, plasterboard nails, wallboard nails, sheetrock nails, cork-insulation nails, lath nails, siding nails, sheeting nails, shingle nails, roofing nails, shade nails, concrete nails, flooring brads, pallet nails, box nails, case nails, basket nails, barrel nails, boat nails, wagon nails, car nails, foundry nails, fence nails, sign nails, hinge nails, clout nails, sinkers, corks, coolers, etc.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 49-A-115.

In a recent U. S. Government publication (1),² sound and efficient nailing practices in home construction are suggested. These recommendations, although backed up by U. S. Forest Products Laboratory test data, are principally based on observed nailing practices, usually a matter of precedent, tradition, or individual judgment, however, as a rule, not fully taking into account the forces to be resisted. The use of plain-shank nails is recommended, presumably because of the unavailability of satisfactory design and test data on and field experience with relatively new nails with spirally or annularly grooved shanks, as shown in Fig. 1. Similarly, because test and design data on such improved

FIG. 1 PLAIN-SHANK, SPIRALLY GROOVED, AND ANNULARLY GROOVED 3 $\frac{1}{2}$ -IN-LONG NAILS

nails never have been available to the designing timber engineer, use of such improved nails for joints of timber structures has not been in the news, although such nails may have been occasionally used for such purposes. In contrast, the design of marine structures by naval architects with such spirally and annularly grooved nails has resulted in their widespread use in boat and ship construction. Automobile manufacturers have long taken advantage of these improved nails for fastening car linings to the body. Box and furniture manufacturers often have been in the position

² Number in parentheses refer to the Bibliography at the end of the paper.

to use these nails to great advantage, in many instances even in place of wood screws. Since 1939 these improved nails have found preferential acceptance for the construction of wooden pallets and were approved in recent recommendations by The National Wooden Pallet Manufacturers Association and Naval Specifications.

Annularly grooved brass, bronze, and stainless-steel nails have been used in carload quantities for butt-nailing asbestos side-wall shingles since early 1935. Lately the wood- and asphalt-shingle contractors have become convinced promoters of the use of grooved nails. Simultaneously, the building industry has become aware of the advantages of these nails for laying floors, fastening of insulation, nailing of siding and millwork. The extended use of these nails for application of metal roofing and building sheets has long been justified by their performance as convincingly exhibited in a recent treatise (2).

A considerable amount of technical information has been made available on plain-shank, barbed, and cement-coated nails. Before preliminary test and design data on spirally and annularly grooved nails had been published (3), first, cement-coated nails (4) and, later, chemically etched nails (5, 6) had been recommended for superior withdrawal resistance immediately after driving. These recommendations had been made despite the fact that these latter types of nails lose some of their holding capacity with time, and change in moisture content of the wood (5, 6).

For proper application of the improved spirally and annularly grooved nails, the necessity arose to obtain test data from which design data could be secured, in line with the generally established trend from empirical to theoretical design of wood structures. Effectiveness and proper use of nails depend upon the following:

- 1 The driving resistance offered, as determined by the energy required to hammer the nail into wood.
- 2 The holding capacity, as observed by the withdrawal resistance of the nail from wood.
- 3 The lateral load-carrying capacity, as found by the resistance of the nail to lateral forces transmitted through the nail to wood.
- 4 The nonsplitting properties, as shown by the resistance to splitting of wood during and after driving of the nail.

These properties are influenced significantly by (a) such nail-production variables as may be specified for material, design, manufacture, and treatment, and (b) such application variables as method of loading, wood species and density, member size and grain direction, moisture content and change in moisture content, time interval between driving and loading, preboring of undersized holes, clinching, and redriving.

This paper cannot present the answer to all nail problems. Its general purpose is to indicate the trends in the field of nailing, to show the special advantages of spirally and annularly grooved nails, and to give proof as to what can be accomplished by research and development work in the field of nailing. Its specific purpose is to determine proper design data for the tested spirally and annularly grooved nails,³ so they may be used to best advantage in wood structures and important wood assemblies.

The test program included evaluation of type of nail (plain-shank, spirally grooved Screwtype with a 60-deg slope of thread, and annularly grooved Stronghold with 0.060-in. spacing from

³ The nails selected for test purposes are general-purpose nails of standard design and conform to standard manufacturing procedure of the producer. Variations from these standards, to satisfy specific requirements, are numerous. Thus the test data obtained in this study may not be directly applied to other nails than those tested, although they are representative spirally and annularly grooved types of nails. Thus the presented data are only directly applicable to the spirally grooved "Screwtype" and annularly grooved "Stronghold" nails manufactured by the Independent Nail & Packing Company, Bridgewater, Mass.

center to center of grooves), size of nail (length and diameter), type of steel (low-carbon and high-carbon), treatment of nail (nonhardened and hardened), surface coating (noncoated and cement-coated), type of nail point (diamond and V), and use of pilot.

Southern yellow pine, white oak, and beech were selected for test purposes as representative for the softwood, open-porous hardwood, and closed-porous hardwood species, respectively. The test planks consisted of select, partially air-dried (20 per cent moisture content), clear, straight-grain, dressed-four-sides, structural 3 × 8-in. and 4 × 8-in. shortleaf pine from Virginia, similar green (46 per cent moisture content) white oak from Virginia, and similar green (45 per cent moisture content) beech from Indiana.

Replicate (duplicate quintuplicate) tests on each test variable were performed with different planks. The nails were spaced perpendicularly to the grain 1 1/4 in. apart, while nail spacing parallel with the grain was 1 1/2 in. In order to facilitate comparative testing with green and dry wood, the testing and matching schedules were prepared in such a way that adjacent locations in the fiber direction of the planks were used for testing with the green and, at a later date, with the dry wood. Nails for tests on withdrawal resistance and lateral load-carrying capacity were driven to 3/4 shank penetration immediately before testing, in order to eliminate any time effect on the test data. Upon completion of these tests, the second series of nails was hammered into the respective adjacent locations for performance of tests upon air-drying of the planks to uniform equilibrium moisture content.

For tests on the driving resistance of nails, a 1000-in.-lb.-capacity nail driver was employed to drive nails with uniform centric impact force into wood, in order to obtain comparative data on the depth of nail-shank penetration as a result of application of a single impact stroke.

For all tests on withdrawal resistance and lateral load-carrying capacity, an Olsen universal testing machine with 1400 and 12,000-lb.-capacity poises was provided with special jigs shown in Figs. 3 and 4.

A universal joint ascertained uniform and centric load application in the direction of the nail axis, provided the nail was driven perpendicular to the plane of the plank. Uniform rate of pulling was attained for all tests on the ultimate withdrawal resistance by the constant motion of the movable crosshead of the testing machine at 0.060 ipm. A test speed of 0.015 ipm was used for the performance of withdrawal tests for which load-deformation data were recorded.

Tests on the lateral load-carrying capacity of nails were performed by loading the projecting part of the nail shank with a free-turning, tight-fitting steel jig placed snugly between nail head and plank. The uniform rate of testing of 0.060 ipm for tests on the ultimate load-carrying capacity was reduced to 0.048 ipm for those tests for which load-deformation data were obtained.

TEST RESULTS

Nail Withdrawal Under Axial-Load Application. The relationship between withdrawal resistance in pounds and withdrawal in inches was determined experimentally in a separate test series for 2 1/2-in.-long, 0.135-in.-diam plain-shank, spirally grooved, and annularly grooved nails, as shown in Fig. 5. They penetrated for two thirds of their shank length into 3 × 8-in. southern yellow pine with a 13.9 per cent average moisture content, 0.57 specific gravity, 14 annual rings per inch, and 30 per cent summerwood.

The observed "slopes" for the three types of nails are similar, that is, 25,000, 26,800, and 22,400 lb/in., respectively. Thus the nails have a similar rigidity in withdrawal, hence cause a similar stiffness of nailed joints within the design range.

As soon as the shank friction of the plain-shank nail was exceeded, that is, upon a withdrawal of 1/10 in. at a load of 420 lb,

the nail pull applied load ing the test, only to a slip friction area tial failure. ping-where constant rate approximate

The spiral a withdrawal defined as th crease consi constant rate during conti nail was inc threaded na 25 per cent lb was obser ing, the low the surface

FIG. 2 D LARLY GRO DRAVAL-T PLAIN-SHA CARBON-S

the nail pulled for a small amount. This resulted in a decrease in applied load under the testing procedure employed. By continuing the test, the applied load could again be increased, however, only to a slightly smaller maximum, since the original friction and friction area between shank and wood were decreased by the initial failure. Further test continuation resulted in successive slipping, whereby the holding capacity decreased step by step at a constant rate, until the test was discontinued at a withdrawal of approximately $\frac{3}{16}$ in.

The spirally grooved nail showed an "initial ultimate load" at a withdrawal of approximately $\frac{1}{32}$ in., if initial ultimate load is defined as the minimum load at which deformation begins to increase considerably with no appreciable increase in load at the constant rate of withdrawal. When the nail was allowed to turn during continuation of the test, the withdrawal resistance of the nail was increased, since a firmer grip between wood fibers and threaded nail shank was attained. At a withdrawal of $\frac{11}{32}$ in., a 25 per cent increase in load beyond the initial ultimate load of 475 lb was observed. When the nail head was prevented from turning, the low-carbon-steel shank of the nail countertwisted near the surface of the plank, as shown in Fig. 2 (left), since during

withdrawal the further inserted part of the shank was forced by the wood fibers to thread itself out of the wood. The resistance offered by the wood fibers to withdrawal under this testing procedure resulted in a 33 per cent increase in withdrawal resistance beyond the initial ultimate load of 535 lb.

The annularly grooved nail attained its ultimate withdrawal

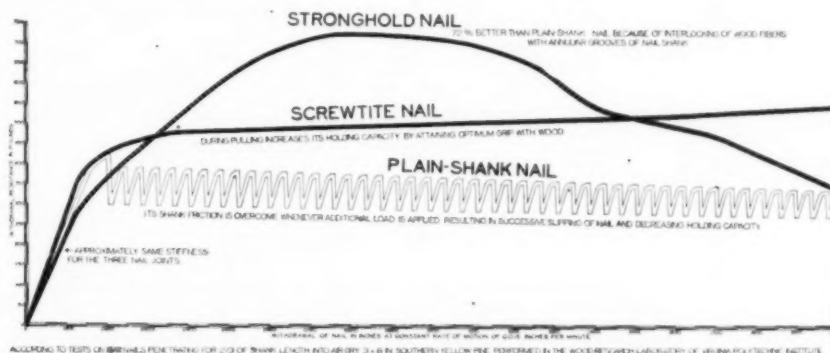

FIG. 5 LOAD-WITHDRAWAL DIAGRAM FOR AXIALLY LOADED LOW-CARBON-STEEL 2 1/2-IN-LONG PLAIN-SHANK, SPIRALLY GROOVED, AND ANNULARLY GROOVED NAILS IN PARTIALLY AIR-DRY SOUTHERN YELLOW PINE

load of approximately 700 lb at a withdrawal of $1/12$ in. Beyond this peak load, its withdrawal resistance continuously decreased with increase in withdrawal. At a withdrawal of approximately $1/8$ in., the holding capacity of this nail approximated that of the plain-shank nail. Withdrawal of such a magnitude is seldom allowable from the design viewpoint. Therefore the greater withdrawal resistance of the annularly grooved nail, as compared with that of the plain-shank nail, cannot be considered lessened by this decrease in holding capacity (beyond its ultimate) if a loading procedure is used similar to that employed in these tests.

Nail Deformation Under Lateral-Load Application. Data on nail deformation during lateral loading of the nail shank are required for the design of nailed wood structures, if the structural design is limited or influenced by the actual deformation of the structure under load. For this test series, the same test material and $2\frac{1}{2}$ -in.-long, 0.135-in.-diam nails were used as for the performance of tests on nail withdrawal. Additional data were obtained for hardened high-carbon-steel nails. The deformation of the nail shank is reported as the motion of a steel loading bar, fitting snugly around the protruding nail shank, relative to a horizontal line on the plank with the nail perpendicular to and intersecting this line. Diagrammatic test data are given in Fig. 6.

The slopes of the load-deformation curves indicate approximately the same stiffness for the three nail types within their design ranges.

The low-carbon-steel plain-shank nail deformed approximately $1/8$ in. before reaching an average maximum load of 620 lb. After having attained this peak load, the nail continued to deform. The shank finally sheared off at the loading edge nearest the plank at a total load of 325 lb and at a total deformation of $7/16$ in. The hardened plain-shank nail was too brittle to resist the shear-stress concentration along the edge of the loading bar. Thus the average ultimate load amounted to only 410 lb.

The low-carbon-steel spirally and annularly grooved nails

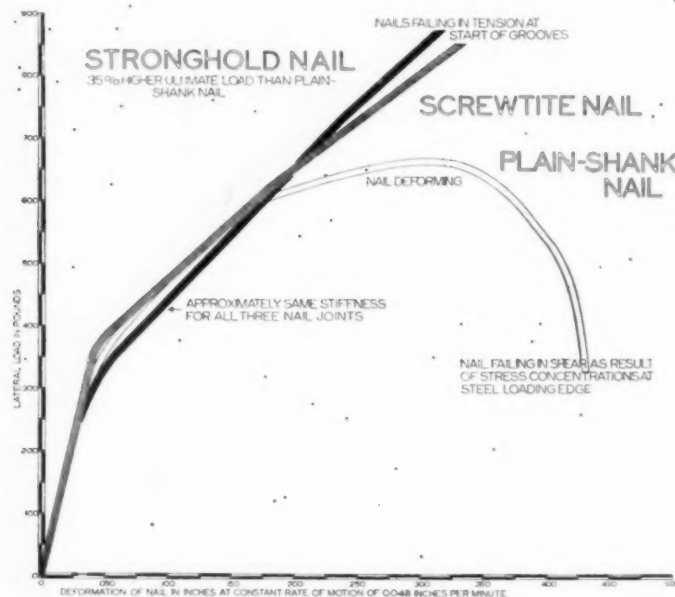

sheared off at the start of the rolled-on shape at an average maximum test load of 840 lb, and a total deformation similar to that found for the plain-shank nail at its maximum test load. Those hardened spirally grooved nails, which did not shear off along the edge of the loading bar, failed $1/2$ in. inside from the plank surface at maximum lateral loads of 820 and 1010 lb, and at a total deformation of $11/32$ in. One of the hardened annularly grooved nails similarly failed at 980 lb and at a similar amount of deformation. Thus on the basis of the limited number of tests performed, spirally and annularly grooved nails appear to have similar rigidity within their complete lateral loading range.

Ultimate Test Data. In Table 1 the driving resistance of nails is given as the ultimate penetration of the nail shank into the plank, corrected for nonuniformity, within a species, in properties of the planks used for testing.

Test data on the ultimate withdrawal resistance for spirally grooved nails are not comparable to those for plain-shank and annularly grooved nails, since the ultimate for spirally grooved nails does not occur within the same range as do the ultimates for plain-shank and annularly grooved nails. On the other hand, the "initial ultimate loads" for spirally grooved and the ultimate loads for plain-shank and annularly grooved nails are attained within a relatively similar range of withdrawal and thus may be considered of a comparable nature. In consideration of this observation, the comparative data given in Table 1 on withdrawal resistance of spirally grooved nails refer to their initial ultimate loads.

The ultimate test data, as observed during lateral loading, were limited by rupture of the nail shanks in 45 per cent of all test cases, that is, in 63 per cent for hardened and in 27 per cent for nonhardened nails. The remaining test nails failed in withdrawal or excessive flexural deformation during lateral-load application.

Both ultimate-withdrawal and lateral-loading data were also

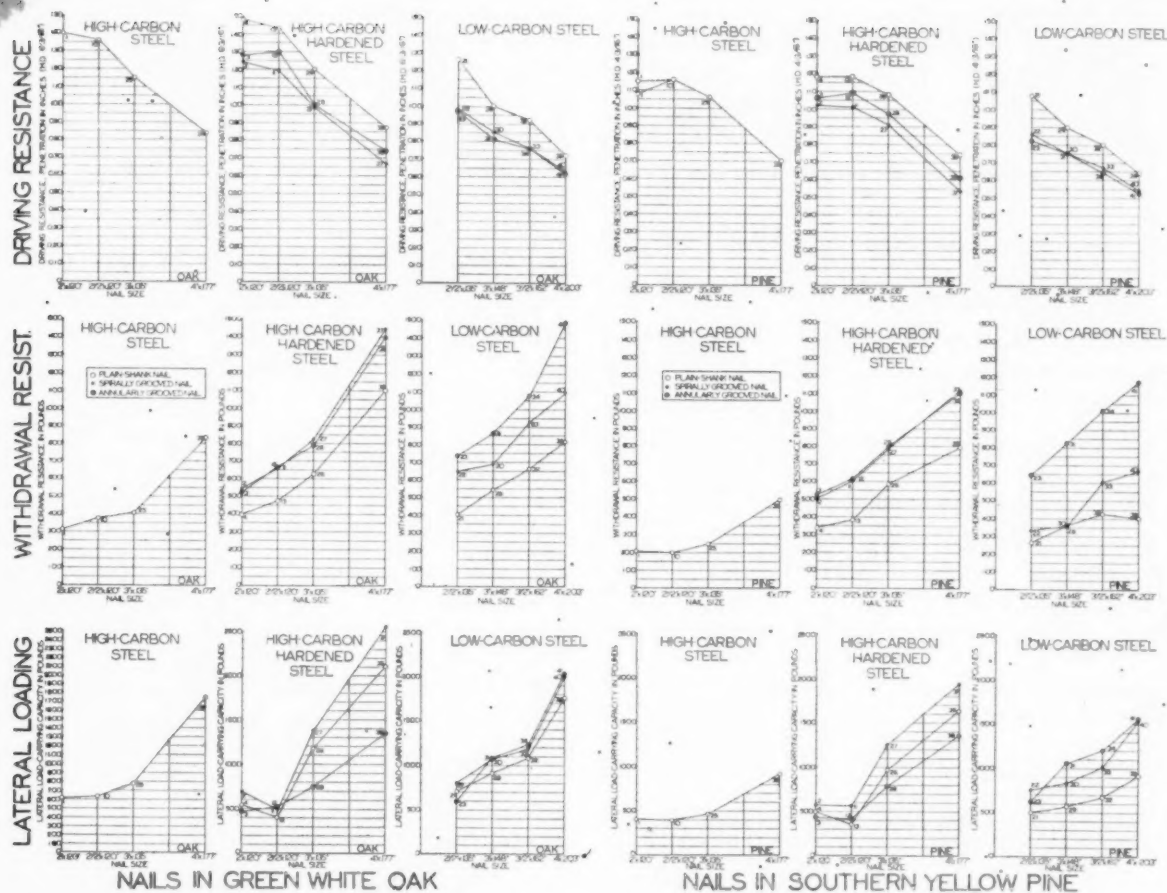

FIG. 7 INFLUENCE OF TYPE OF NAIL ON DRIVING RESISTANCE, WITHDRAWAL RESISTANCE, AND LATERAL LOAD-CARRYING CAPACITY OF 2, 2 1/2, 3, 3 1/2, AND 4-IN-LONG PLAIN-SHANK, SPIRALLY GROOVED, AND ANNULARLY GROOVED NAILS IN GREEN WHITE OAK, GREEN BEECH, AND PARTIALLY AIR-DRY SOUTHERN YELLOW PINE

corrected for nonuniformity in plank properties, if different planks within a species showed variations in their nail-withdrawal resistance and lateral load-carrying capacity.

INFLUENCE OF DESIGN VARIABLES

Nail Type. Comparative tests on driving resistance, withdrawal resistance, and lateral load-carrying capacity were performed with low-carbon-steel and hardened high-carbon-steel plain-shank, spirally grooved, and annularly grooved nails. The test results are given in Table 1 and graphically presented in Fig. 7. Because of their increased contact areas and frictional resistance between nail shank and surrounding wood, the grooved nails provided a larger withdrawal resistance and lateral load-carrying capacity than the plain-shank nails. These increases, however, were combined with an increase in driving resistance, although the latter increase proved to be somewhat smaller than those for withdrawal resistance and lateral load-carrying capacity.

The average driving resistance of the low-carbon-steel and hardened high-carbon-steel spirally grooved nails in green oak was 19 and 18 per cent, that in green beech was 20 and 21 per cent, and that in partially air-dry southern yellow pine was 19 and 16 per cent greater, respectively, than that of the plain-shank nails.

The average driving resistance of the corresponding annularly grooved nails in oak was 20 and 13 per cent, that in beech was 22 and 13 per cent, and that in southern yellow pine was 21 and 11 per cent greater, respectively. Thus the average driving resistance of spirally and annularly grooved nails tested was between 1/5 and 1/4 greater than that of the plain-shank nails.

The average withdrawal resistance of the low-carbon-steel and hardened high-carbon-steel spirally grooved nails in oak was 39 and 34 per cent, that in beech was 17 and 16 per cent, and that in southern yellow pine was 34 and 43 per cent greater, respectively, than that of the plain-shank nails. The average withdrawal resistance of the respective annularly grooved nails in oak was 72 and 30 per cent, that in beech was 27 and 12 per cent, and that in southern yellow pine was 50 and 45 per cent greater.

The average lateral load-carrying capacity of low-carbon-steel spirally and annularly grooved nails in oak was 14 and 12 per cent, that in beech was 31 and 40 per cent, and that in southern yellow pine was 52 and 64 per cent greater, respectively, than that of the plain-shank nails; that of the hardened high-carbon-steel spirally grooved nails in oak was 21 per cent, in beech was 3 per cent, and in pine was 25 per cent greater. By use of more satisfactory heat-treating procedures, considerable improvement might have been attained in the lateral load-carrying capacity of

these hardened high-carbon-steel nails. To this end, improved equipment has been installed by the nail manufacturer.

Nail Size. According to authoritative data (6), the withdrawal resistance per inch of penetration of plain-shank nails varies directly with the nail diameter. One of the exceptions is the withdrawal resistance, e.g., of $3\frac{1}{2}$ and 4-in-long plain-shank nails in southern yellow pine, which is 5 and 10 per cent smaller, respectively, than if computed according to the foregoing correlation. Furthermore, according to this reference, the lateral load-carrying capacity of plain-shank nails varies with the 1.5th power of the nail diameter.

Comparative tests on driving resistance, withdrawal resistance, and lateral load-carrying capacity were performed with $2\frac{1}{2}$, 3, $3\frac{1}{2}$, and 4-in-long low-carbon-steel plain-shank, spirally grooved, and annularly grooved nails, and with 2, $2\frac{1}{2}$, 3, and 4-in-long nonhardened high-carbon-steel plain-shank nails, and hardened high-carbon-steel plain-shank, spirally grooved, and annularly grooved nails. The test data are graphically presented in Figs. 8 and 9, in comparison with those advanced in reference (6) for low-carbon-steel common wire nails. This comparison is limited in value, since common wire nails are made of a wire with a slightly different diameter from the tested nails.

With increase in shank diameter, that is, the wire gage from which the nail was made, average driving resistance of both spirally and annularly grooved nails increased at a similar rate. This

increase, however, was slightly larger than that of the plain-shank nail driven into southern yellow pine and, especially, into oak. On the basis of the relatively uniform test data, it may be justified to assume a curvilinear relationship between shank diameter and depth of penetration for plain-shank nails, and a similar curvilinear relationship for grooved nails.

The increase in withdrawal resistance per inch of penetration with increase in shank diameter of low-carbon-steel plain-shank and grooved nails was somewhat smaller than expected, according to reference (6) for low-carbon-steel plain-shank nails. Although some of the data are somewhat erratic, a general trend of curvilinear relationship may be expected, particularly if grand average data for increase in withdrawal resistance of —2, 7, and 19 per cent for nails in oak, of 4, 8, and 22 per cent for nails in beech, and of 5, 18, and 13 per cent for nails in southern yellow pine are compared with increases in shank diameters of 10, 20, and 50 per cent.

The average withdrawal resistance per inch of penetration of the high-carbon-steel 3-in-long nails was only slightly larger, and that of the 4-in-long nails in oak 39 per cent, in beech 48 per cent, and in southern yellow pine 18 per cent larger than that of the 2 and $2\frac{1}{2}$ -in-long nails. The withdrawal resistance of some of the 3-in-long and, in particular, that of almost all 4-in-long nails should have been larger, according to the correlation suggested in reference (6), for low-carbon-steel plain-shank nails. The excessive brittleness of some of the test nails may have been of some influence on these data.

While the increase in lateral load-carrying capacity of low-carbon-steel plain-shank and spirally grooved nails in southern yellow pine, with increase in diameter, was similar to that expected, according to the general formula advanced in reference (6), the increase in capacity of these nails in oak and beech and of spirally grooved nails in oak, beech, and southern yellow pine was considerably larger. Thus with an increase in diameter of 10, 20, and 50 per cent for 3, $3\frac{1}{2}$, and 4-in-long nails, on the basis of comparison with the $2\frac{1}{2}$ -in-long nail, the respective ratios of average increases in capacity for plain-shank and spirally grooved nails in southern yellow pine were 12:34:98, in beech were 80:80:236, and in oak were 32:50:149; those for annularly grooved nails in southern yellow pine were 71:87:150, in beech were 21:45:165, and in oak were 81:107:240.

The increase in lateral load-carrying capacity with increase in diameter of most of the high-carbon-steel nails tested was also considerably larger than that expected, according to the general formula presented in reference (6) for low-carbon-steel plain-shank nails. The erratic nature of some of the test data is explained by the considerable variation in brittleness of these nails.

The relatively small increase in efficiency with increase in shank diameter of some of the grooved nails, in comparison with that of the plain-shank nails, such as in withdrawal resistance in green beech, may be explained by the uniformity in spacing of spiral and annular grooves for all nail sizes. Smaller center-to-center spacing of the grooves of the large-size nails might have increased their efficiency, although to date, no data have been obtained to substantiate such an assumption.

Nail Point. Nails tapered to and terminating in a flat point do not split wood as much as nails with a sharp or diamond point. The withdrawal resistance of nails with a tapered and flat point is equal in dense wood, though, smaller in less dense wood than that of the corresponding nail with a sharp point. Splitting of wood by a nail may also be prevented by use of a shank point with a short wedge having a blunt end, such as the V-point. Although the angle of the wedge-point axis to the wood-fiber direction may be of influence on the efficiency of this nail, all V-point nails were driven without consideration being given to the direction of the wedge axis.

FIG. 8 EFFICIENCY DIAGRAM, WITH RESPECT TO WIRE DIAMETER OF NAIL SHANK, FOR PLAIN-SHANK, SPIRALLY GROOVED, AND ANNULARLY GROOVED LOW-CARBON-STEEL NAILS IN GREEN WHITE OAK, GREEN BEECH, AND PARTIALLY AIR-DRY SOUTHERN YELLOW PINE ACCORDING TO GRAND AVERAGES FOR DECUPLE TESTS

Comparative tests were performed with 2 and 2½-in-long diamond-point and V-point, high-carbon-steel nonhardened plain-shank and hardened spirally and annularly grooved nails, manufactured from the same wire strand, and driven into green white oak and partially air-dry southern yellow pine. The V-point, in comparison with the diamond point, resulted in a 9, 8, and 4 per cent greater average driving resistance and a 10, 5, and 5 per cent smaller average withdrawal resistance for the non-hardened plain-shank, hardened spirally grooved, and hardened annularly grooved nails, respectively. The lateral load-carrying capacity of the nonhardened plain-shank nail with V-point was 4 per cent smaller than that of the diamond-point nail. The lateral load-carrying capacity of the hardened grooved nails with V and diamond points was influenced too much by variations in nail brittleness to yield satisfactory comparative data.

With few exceptions, the effect of the V-point was consistent for all tests on the driving resistance, withdrawal resistance, and lateral load-carrying capacity. However, the influence of the V-point, in comparison with that of the diamond point, on the foregoing properties was relatively small, thus insignificant from the practical viewpoint.

Shank Pilot. For ease in initial driving of nails with grooved shanks, a pilot may be used, that is, for a short length from the nail point, the nail shank is plain and grooving starts only beyond that length. The length of the pilot may vary. For tests on the 2½-in-long hardened high-carbon-steel grooved nails with a pilot, a pilot length of ⅜ in. was used.

According to the comparative data for spirally and annularly grooved nails, the pilot resulted in a 2.5 per cent greater average driving resistance and a 5 per cent smaller average withdrawal resistance. In view of the considerable variation in brittleness of the test nails, fully comparative data could not be obtained on the

lateral load-carrying capacity of nails with and without pilots.

Thus it appears that as a short pilot was used for these comparative tests, it did not have any appreciable influence on both driving and withdrawal resistance of 2½-in-long, hardened high-carbon-steel spirally and annularly grooved nails.

Steel Composition. Both "regular" low-carbon steel, SAE 1010, and high-carbon steel, SAE 1065, were used for the manufacture of the tested nails. Comparative data were obtained on the driving resistance, withdrawal resistance, and lateral load-carrying capacity of 2½, 3, and 4-in-long plain-shank nails made from both steels, with the high-carbon-steel nails having 11.2, 8.8, and 12.8 per cent smaller diameters, respectively.

The average driving resistance of high-carbon-steel nails was 7 to 18 per cent, with a grand average of 12 per cent, smaller than that of the low-carbon-steel nails. An exception was the 3-in-long high-carbon-steel nail in beech with a 30 per cent larger driving resistance. The average withdrawal resistance of the high-carbon-steel nails was from 34 per cent smaller to 22 per cent larger, with a grand average of 10 per cent smaller, than that of the low-carbon-steel nails. Similarly, the lateral load-carrying capacity of the high-carbon-steel nails was from 25 per cent smaller to 44 per cent larger, with a grand average of 7 per cent, smaller than that of the low-carbon-steel nails.

Thus, because of the smaller diameters of the high-carbon-steel nails, as compared to the diameters of the low-carbon-steel nails of the same types and lengths, the high-carbon-steel nails were somewhat easier to drive and had a smaller withdrawal resistance and lateral load-carrying capacity than the respective low-carbon-steel nails.

Heat-Treatment. High-carbon-steel nails may be hardened to increase their buckling resistance during driving, their withdrawal resistance and lateral load-carrying capacity during use. Thus some of the high-carbon-steel nails were heat-treated at 1500 to 1600 F for 28 min, quenched in an oil bath, and tempered at 550 F for an additional 28 min. The nails thus treated varied considerably in brittleness although made from the same wire strand and issuing from the same nail batch, with some of the nails failing as a result of their brittleness and others failing only in exceeding their withdrawal resistance.

Comparative data were secured on the driving resistance, withdrawal resistance, and lateral load-carrying capacity of 2, 2½, 3, and 4-in-long high-carbon-steel, nonhardened and hardened plain-shank nails.

The average driving resistance of the hardened nails was from 2 per cent larger to 9 per cent smaller, with a grand average of 3 per cent smaller than that of the nonhardened nails. The average withdrawal resistance of the hardened nails was 11 to 142 per cent, with a grand average of 50 per cent larger than that of the nonhardened nails. The lateral load-carrying capacity of the hardened nails was from 36 per cent smaller to 109 per cent larger, with a grand average of 21 per cent larger than that of the nonhardened nails. While the driving resistance of hardened nails was almost consistently, however, from the practical viewpoint, insignificantly smaller, the withdrawal resistance of the hardened nails was consistently larger than that of the nonhardened nails. The considerable variation in brittleness is the explanation for the relatively large variation in data on both the withdrawal resistance and lateral load-carrying capacity of hardened nails. However, since as a result of heat-treatment both withdrawal resistance and lateral load-carrying capacity of some of the nails were increased more than 100 per cent, it should be possible to increase consistently to a considerable degree both withdrawal resistance and lateral load-carrying capacity by use of fully satisfactory hardening methods with equipment only lately installed by the nail manufacturer.

Cement Coating. According to information given in reference

FIG. 9 EFFICIENCY DIAGRAM, WITH RESPECT TO WIRE DIAMETER OF NAIL SHANK, FOR PLAIN-SHANK, SPIRALLY GROOVED, AND ANNULARLY GROOVED HIGH-CARBON-STEEL NAILS IN GREEN WHITE OAK, GREEN BEECH, AND PARTIALLY AIR-DRY SOUTHERN YELLOW PINE ACCORDING TO GRAND AVERAGES FOR DECUPLE TESTS

(6) the withdrawal resistance of plain-shank nails immediately after driving into light wood may be 85 to 100 per cent larger if the nails are properly cement-coated, while, with increase in wood density, the benefit of cement coating decreases to practically no advantage over noncoating.

Comparative tests were performed on the driving resistance, withdrawal resistance, and lateral load-carrying capacity of 2 1/2-in-long low-carbon-steel plain-shank nails and hardened high-carbon-steel spirally and annularly grooved nails. The cement-coating compound⁴ used consisted of synthetic resin treated with linseed oil. It contained 65 per cent, by weight, petroleum naphtha as volatile carrier. It was applied in a tumbling process at normal temperature and uniformly covered the whole nail.

The average driving resistance of the noncoated and coated

⁴ No. V-5071 Elastic Nail Coating by the M. B. Suydam Division of Pittsburgh Plate Glass Company.

nails did not vary to any large extent. Cement coating increased the average withdrawal resistance of the plain-shank nail in oak 28 per cent, in beech 6 per cent, and in southern yellow pine 65 per cent. On the other hand, cement-coating of hardened high-carbon-steel spirally and annularly grooved nails was of no effect on their withdrawal resistance. The lateral load-carrying capacity of the coated plain-shank nail in oak was 5 per cent, in beech was 19 per cent, and in southern yellow pine was 28 per cent greater as a result of application of cement coating. The variation in brittleness of the hardened spirally and annularly grooved nails did not make it possible to obtain reliable data on the influence of cement coating on the lateral load-carrying capacity of these nails, although the coated spirally grooved nail showed consistently larger values than the noncoated nail. However, since the withdrawal resistance of these nails was not increased as a result of cement-coating, this increase in lateral load-carrying capacity may not be fully attributable to the coating.

The foregoing data on the withdrawal resistance of plain-shank nails are in general agreement with the information advanced in reference (6) for plain-shank nails. These data also indicate that cement-coating of spirally and annularly grooved nails may not be justified for purposes of improving their withdrawal resistance.

SUMMARY

1 With relatively small increases in driving resistance of nails, large increases can be expected in both withdrawal resistance and lateral load-carrying capacity.

2 Spirally and annularly grooved nails offer larger withdrawal resistance and lateral load-carrying capacity than plain-shank nails. Annularly grooved low-carbon-steel nails offer a larger withdrawal resistance than spirally grooved low-carbon-steel nails, while the withdrawal resistance of spirally and annularly grooved hardened high-carbon-steel nails is approximately the same.

3 Typical data on the effectiveness of spirally and annularly grooved nail shanks in comparison with plain nail shanks are presented in Table 2.

TABLE 2 COMPARISON OF PER CENT EFFECTIVENESS OF LOW-CARBON-STEEL, DIAMOND-POINT, 2 1/2-IN.-LONG, 0.135-IN.-DIAM. PLAIN-SHANK, CEMENT-COATED PLAIN-SHANK, SPIRALLY GROOVED, AND ANNULARLY GROOVED NAILS ON BASIS OF COMPARISON WITH RESPECTIVE NON-COATED PLAIN-SHANK NAIL

Wood species	Property	Plain-shank nail Non-coated	Cement-coated nail	Spirally grooved nail	Annularly grooved nail
In green	Driving resistance	100	100	122	123
	Withdrawal resistance	100	128	161	183
white oak	Lateral load-carrying capacity	100	105	114	85
In green	Driving resistance	100	101	119	123
	Withdrawal resistance	100	106	136	152
beech	Lateral load-carrying capacity	100	119	136	180
In partially air-dry	Driving resistance	100	96	120	124
southern pine	Withdrawal resistance	100	166	125	244
	Lateral load-carrying capacity	100	128	150	124

4 Both under withdrawal and lateral load, plain-shank and spirally or annularly grooved nails have similar rigidity within their design ranges; thus cause similar stiffness of nailed joints.

5 Under constant rate of withdrawal, plain-shank nails retain, within given limits, a slowly decreasing holding capacity somewhat below the ultimate holding capacity; spirally grooved nails continue to increase their holding capacity, although at a decreased rate of increase, after the "initial ultimate withdrawal resistance" has been reached; annularly grooved nails reach a considerably greater ultimate withdrawal resistance at a larger withdrawal than plain-shank and spirally grooved nails, while this withdrawal resistance decreases at a similar rate to that of increase up to the ultimate.

6 Under lateral load, the ultimate lateral load-carrying capacity of plain-shank and spirally or annularly grooved nails is reached at approximately the same amount of deformation.

7 Curvilinear relationships may be assumed between nail-shank diameter and both driving resistance and withdrawal resistance for plain-shank nails. Similar curvilinear relationships seem to exist for spirally and annularly grooved nails. The general correlation between nail-shank diameter and lateral load-carrying capacity, as presented in reference (6), seems to be somewhat conservative for plain-shank and spirally grooved nails in green white oak, green beech, and partially air-dry southern yellow pine.

8 The V-point, in comparison with the diamond point, has little effect on the driving resistance, withdrawal resistance, and lateral load-carrying capacity of plain-shank and spirally or annularly grooved nails.

9 A short pilot for grooved nails does not have any appreciable influence on either driving or withdrawal resistance.

10 High-carbon-steel nails, having smaller shank diameters

than low-carbon-steel nails of the same lengths, are, type for type, somewhat easier to drive and have correspondingly smaller withdrawal resistance and lateral load-carrying capacity than low-carbon-steel nails with their larger diameters.

11 Although the driving resistance of hardened nails is similar to that of nonhardened nails, the withdrawal resistance and lateral load-carrying capacity of hardened nails can be considerably larger.

12 Cement coating results in considerably increased withdrawal resistance of plain-shank nails immediately after driving into the low-density southern yellow pine and an almost negligible increase in withdrawal resistance for high-density beech. However, cement coating does not increase withdrawal resistance or lateral load-carrying capacity of spirally or annularly grooved nails.

13 Because of the considerable difference in moisture content, the average driving resistance, withdrawal resistance, and lateral load-carrying capacity of nails in green white oak and beech on the one hand, and partially air-dry southern yellow pine on the other hand, did not differ greatly and as much as

would be expected if the nails were tested in these species with like moisture content (7).

14 Driving resistance and withdrawal resistance increase with increase in wood density according to somewhat similar trends (7).

15 As a result of variation in physical structure of the plank, driving resistance, withdrawal resistance, and lateral load-carrying capacity may vary within the same plank cross section, even if the lumber is free of growth irregularities (7).

ACKNOWLEDGMENT

This study was performed in the VPI Wood Research Laboratory under the auspices of the VPI Research Foundation, Inc., and under the sponsorship of the Independent Nail & Packing Company of Bridgewater, Mass., manufacturer of the spirally grooved Screwite and the annularly grooved Stronghold nails.

Discussion

T. D. PERRY.⁴ The nail is one of the most common items used in all kinds of woodworking, one of our largest industries. It is surprising that so little has been investigated, technically, with regard to the gripping power of nails having different shapes of shanks.

Excellent as this paper is, there are two points which need clarification in this as well as in the author's earlier paper on the subject.

Simplify the conclusions, by emphasizing major factors at the expense of less important ones, or break the results down into sections, so that the number of variables in each bracket is much reduced. Reading technical papers is no novelty to me, but I have to confess considerable confusion, even after a careful reading of this paper. Reading rapidly or scanning would not improve the casual reader's conclusions. The facts are there but they do not stand out clearly against the background of lengthy testing procedure.

Supplement the strength data by analyzing the economic factors. If 8 lb of grooved shank nails are needed to carry the same load as 10 lb of common plain shank nails, what is the relative cost of the two lots? In other words, and in the last analysis, the dominating reason for adopting such nails would be either more strength at the same cost, or equal strength at less cost.

H. J. STONE⁵ states that with respect to the use of grooved nails in the field of building construction, the most important point is that ordinary nails are not nearly strong enough to equal the structural strength of the materials they fasten. To put this in another way, the frame used in the average home is, according to our tests, up to 5 times as strong as its fastenings. However, if properly grooved nails are used, their holding power can exceed the strength of the lumber they fasten, with the result that the frame of a house assembled with properly grooved nails will be fractured before the nails have yielded. It seems obvious that, since a house is ultimately not stronger than the fastenings which were used in its assembly, these fastenings should be as strong, if not stronger, than the lumber used in the construction of the house.

While it may be argued that most houses are never subjected to extraordinary stresses, there are in almost all sections of the country periods of high winds, extremes of temperatures, and other conditions which cause severe stresses on the house structure. These stresses often result in cracks, warpage, and distortions with resulting sticking of windows, door frames, and other comparatively minor distortions, which may result in repair bills, any one of which may exceed the additional cost of properly grooved nails.

The advantages of grooved nailing also apply to roofing, wood-finishing, door and window frames, and other elements which often deteriorate and cause trouble. An asphalt-shingle roof fastened with properly grooved roofing nails will never leak due to nail popping. Here again, a single roof leak may be more costly than the entire differential in cost between annularly grooved nails and ordinary roofing nails.

In the case of the grooved flooring nails, as compared with

conventional nails, we have experiences with spirally grooved nails going back 15 or 16 years. We have no record of failure during that period of time. On the other hand, floors nailed with either conventional cut nails or common wire brads will in time squeak, buckle, and ultimately require re-nailing and re-finishing.

Many of the cracks in walls and ceilings can be traced to failure of fastenings in the frame of a house and consequent settling of frames or distortion of walls. These conditions may be avoided with use of properly grooved nails which are proved in tests to exceed the strength of common nails as much as 1200 per cent.

If the contractor or home owner desires to offset the slight additional cost of properly grooved nails, this may be done by sheathing the house with one of several types of synthetic sheathing materials. While such materials are not as effective as boarding when common nails are used, they may safely be used if the house structure is assembled and the sheathing itself applied with the respective grooved nails. The use of these grooved nails also allows the use of lower grades of lumber without reducing the ultimate strength of the building itself.

AUTHOR'S CLOSURE

With respect to Mr. Perry's comments, it may be stated that this paper is to serve a twofold purpose. It is (a) to make available to the average engineer general information on the advantages of using improved nails; and (b) to present detailed data to the nail user concerned with a large number of variables of little interest to the average engineer. The information which may be too detailed for the former, may contain too little data for the latter. Thus a relatively large amount of information had to be crowded into a given space. For those wishing to obtain additional information, parts or complete copies of reference (7)⁷ can be made available.

Since presentation of this paper, a considerable amount of additional information on improved nails and their effects has been obtained. To those interested in this information, a supplement to the Bibliography appears at the end of this closure.

Reference (10) contains a partial summary of fully comparative information on delayed nail-holding properties, as referred to in the paper and scheduled for later presentation. Thus it shows the effect of change in moisture content and elapsed time after nail driving on the test variables under discussion.

With respect to the economic aspects created by the mass-production of grooved nails, Mr. Perry overlooked the aspect of considerably increased service at somewhat increased cost. In this case, this aspect can be combined with better service at the same cost or equal service at less cost, since the better service rendered by the individual grooved nail makes it possible to reduce, under given conditions, the number of nails hitherto required.

One of the cases in which considerably better service can be obtained at even decreased cost for grooved nails, is that of the spirally grooved Screwite flooring nails. In this particular case, 50 lb of grooved nails replace 100 lb of cut nails, with an increase in nail-holding power of 40 per cent, combined with a simultaneous saving of 28 per cent of the cost of the cut nail.

For a more complete analysis of the economic aspects of use of grooved nails, a cost analysis (Table 3) is presented which was advanced for a 50-ft X 24-ft \$10,000 five-room house with attached garage.

Thus, at a cost of \$10,000 for this house, the cost of all nails amounts to \$65.70 or 0.657 per cent if of the plain-shank type, and to \$106.25 or 1.0625 per cent if of the grooved type.⁸ In other

words, for an increase of \$40.55 or less than 1/2 per cent of the total cost of the house, all the following advantages can be obtained, according to data presented in the paper and in references (8, 9, 10, 11). It is not a necessity, of course, to replace all plain-shank nails with grooved nails. To date, replacement for individual applications has been more or less the case. On the other hand, with the increased amount of knowledge as to the beneficial effect of use of grooved nails, total replacement of nails must be given consideration under certain conditions. The advantages follow:

1 For the increased expenditure of \$20.03 or 0.2 per cent of the total cost of the house given as an example, the unsheathed framing can offer a 4 to 6 times greater lateral-thrust resistance, with the frame joints possibly even stronger than the framing lumber (9).

2 For a saving of \$1.09, as a result of the use of 15 lb of spirally grooved Screwwite flooring nails instead of the twice as heavy cut flooring nails, the flooring and stair treads can be more easily and quickly laid; under normal conditions do not come loose, squeaky or springy, cup or buckle; split tongues can be averted; whereby 220 and 40 per cent, respectively, greater withdrawal resistances are obtained if comparison is made with the same-size plain-shank flooring brads and cut flooring nails (11).

3 For an increased expenditure of \$1.05, all the siding may be fastened in such a way that the nails will not "creep" or "pop"; thus the siding remains firmly fastened to the structure.

4 For an increased expenditure of \$6.31, assurance may be had that none of the wood or asbestos shingles will come loose since the use of grooved nails results in a 250 per cent greater holding power than attained by use of corresponding plain-shank nails.

5 For an increased expenditure of \$5.94 for fastening asphalt-roofing shingles, assurance may be had that the nails will retain the shingles continuously tightly fastened as a result of the 50 per cent greater axial withdrawal resistance of the grooved nails in comparison with the plain-shank nails.

6 For an increased expenditure of \$6.21, the plaster lath may be fastened permanently and firmly to the framework because of the 40 per cent increased holding power of the annularly grooved nails. Thus the possibility of formation of any cracks in plaster is considerably decreased.

7 For an increased expenditure of \$2.10 for casing and finishing nails, the woodwork should never come loose. Thus a satisfactory fastening of all interior woodwork even after aging of the structure can be assured.

The cost increases cited result from the use of an equivalent number of properly grooved nails to replace plain-shank nails. In many cases, a smaller number of grooved nails may be used without detrimental effect. Thus the small increases in expenditure may even be decreased.

All the improvements in the structure immediately after erection and during its life, and the decreased cost of maintenance and repair, resulting exclusively from the use of grooved nails, can be attained for a cost amounting to less than 1/2 per cent of the total cost. This small difference in initial cost may be considered "an insurance premium of the entire value of the house for its lifetime, which will guarantee that the house will not deteriorate within its expected lifetime."

Although tables indicating the efficiency of grooved nails in comparison with plain-shank nails, as based on holding capacity per dollar value, could be presented according to the data made available in this and other papers (10, 11), it is believed that the foregoing cost analysis for nails in home construction answers the question raised by Mr. Perry as to the economic aspects of the use of grooved nails.

Head and Flow Observations on a High-Efficiency Free Centrifugal-Pump Impeller

By W. C. OSBORNE¹ AND D. A. MORELLI,² PASADENA, CALIF.

A series of studies of the flow through the various components of hydrodynamic machinery is in progress in the Hydraulic Machinery Laboratory of the California Institute of Technology. Observations have been made on an impeller patterned after the Grand Coulee design. The impeller was operated as an isolated unit hydraulically free of the casing. The flow pattern at the discharge has been determined quantitatively for one flow rate, and a head-capacity curve for the impeller has been obtained. This paper constitutes a report on the findings up to the present.

INTRODUCTION

IN the past most of the experimental work carried on in the field of rotating machinery has dealt with the machine as a whole, and because of the technical difficulties involved, comparatively little has been done to determine the performance characteristics of the individual elements which make up the whole. As a rough classification, such a machine can be thought of as consisting of three parts, namely, (a) the stationary inlet member, (b) the rotating member, and (c) the stationary outlet member.

Some empirical work has been carried out in which various rotating members have been tested with the same stationary members and vice versa, but the test results obtained in these cases have been referred to the performance of the combination as a complete machine, and the effect of changes in the individual member has been inferred only through the effect of such changes on the over-all performance. Several laboratories, particularly those of Spannhake, Thoma, and Pfeleiderer, in Germany (1-9),³ have undertaken experimental investigations of the detailed characteristics of the flow in the rotating passages, and a few workers have explored the flow during its transition from the rotating member to the case. In practically all instances, however, the experimental machine has been greatly simplified, usually to the point of making the runner two-dimensional. The gain from such simplification has been twofold, namely, the experimental difficulties have been lessened appreciably, and the possibility of parallel analytical studies has been improved. Unfortunately, the losses accompanying the simplification have included large decreases in efficiency, lowered resistance to cavitation, and a general lack of similarity to the performance characteristics of modern hydraulic machines.

Much effort has been devoted to the development of a satisfactory analytical treatment of the flow in hydraulic machines.

Contributed by the Hydraulic Division and presented at the Annual Meeting, New York, N. Y., November 27-December 2, 1949, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 49-A-108.

Considerable progress has been made in the analysis of the axial-flow machine based upon airfoil theories, especially in the zone of efficient operation. However, for abnormal operating conditions even in the axial-flow machines, and for all conditions in the machines having appreciable components of radial flow, the presently known analytical methods leave much to be desired. If the performance of the individual elements of machines having good characteristics and high efficiencies could be obtained experimentally, and especially if the details of the flow could be determined, as well as the over-all characteristics of the elements, it would greatly enlarge the possibilities of developing a satisfactory analytical treatment and at the same time improve design possibilities through the use of more detailed empirical information.

In an effort to meet this need, a project has been initiated at the Hydrodynamics Laboratory of the California Institute of Technology under the sponsorship of the Office of Naval Research for the primary purpose of making detailed studies, both experimental and analytical, of flow through various components of well-designed modern hydraulic machines. Since the existing facilities of the Hydraulic Machinery Laboratory (10) were not readily adaptable to the type of experimental work anticipated, a smaller more suitable laboratory was constructed.

LABORATORY FACILITIES

The project is located on the mezzanine floor of the Hydraulic Machinery Laboratory. The equipment is arranged to provide a flow of water in a closed circuit which is shown schematically in Fig. 1 and which consists essentially of three principal sections. One section functions primarily as a supply reservoir and includes the necessary equipment to deliver and meter a steady flow of water at various pressures and flow rates. It includes the reservoir and service pump, the Venturi meters and the throttle valve. This part of the circuit is independent of whatever test arrangement is made.

The second section functions principally as a distribution circuit and includes an adaptable arrangement of distributing headers, valves, and piping which may be arranged in various combinations to carry the flow from the throttle valve to and from the test elements in the particular manner and direction required by the unit under observation. Fig. 1 shows two of the several flow circuits possible. The major portion of this section is expendable and may be modified as the research requires.

The test stand is the third part of the circuit. Here are provided facilities for mounting, operating, and testing hydraulic-machine elements. The principal parts are the approach piping, the test basin, and the vertical dynamometer. These components are all in duplicate and thus allow two different studies to be run alternately and effect a great saving of time. Fig. 2 shows the test equipment as arranged for the photographic studies herein reported. One of the vertical dynamometers has been removed and replaced by a centerless impeller-drive mechanism to allow a full view of the impeller. Windows have been installed in the test basin to facilitate lighting and provide additional observation points. Fig. 3 presents the parallel test setup on the opposite side of the test stand. With this arrangement over-all

Fig. 1 DIAGRAM OF MAIN AND AUXILIARY FLOW CIRCUITS

head-capacity characteristics of the impeller were determined.

The project is a self-contained unit and can be operated independently of the other equipment in the building. However, to avoid duplication of equipment, the three Venturi meters may be connected to the main calibrating circuit of the Hydraulic Machinery Laboratory (10) and the existing facilities used for calibration. Fig. 2 shows the two points of interconnection.

The apparatus covers the following ranges:

- 1 Flow rates up to 4 cfs with a head differential of 66 ft at the test unit.
- 2 Power input or absorption up to 30 hp.
- 3 Dynamometers capable of rotative speeds of 100–2000 rpm in either direction.

The physical size of the test elements is not rigidly fixed. However, rotating channels up to 12 in. diam and diffuser or volute casings up to 30 in. diam may be accommodated.

Although the conventional opaque metal cast elements can be used in some test work, techniques have been developed at the laboratory for precision manufacture of these elements from transparent materials such as lucite. This not only makes possible the use of the various photographic techniques (12, 13) which have been developed and found to be extremely useful in observing and analyzing flow phenomena in the Hydrodynamics Laboratory (11), but it also offers advantages of controlled dimensions and guarantees symmetry and reproducibility to a degree essential for precise test work, which, ordinarily, are unattainable with standard cast elements.

OBJECT OF TESTS

The impeller of a centrifugal pump was chosen as the first

machine element to be examined. The rotating member was selected since it may be considered as the primary element of the pump; the principal interchange of energy between the machine and the fluid takes place in its rotating passages. The initial studies were confined to observations of the flow pattern at the discharge section of the impeller and to determinations of the over-all head-capacity characteristics of the impeller running free of its case. The discharge section of a modern medium-specific-speed impeller lends itself more readily to observation than does the inlet section and hence was selected as a logical starting point for a series of investigations which eventually will cover the entire impeller passage. Likewise, the head-capacity is the beginning of a series of studies designed to cover the complete over-all operating characteristics of the impeller. It is the purpose of this paper to report the findings of these initial studies and to present the tentative conclusions that have been drawn.

THE TEST IMPELLER

The test impeller used was very similar in design to the Grand Coulee pump impeller. This pump is a high-efficiency unit of medium specific speed, $N_s = 100$ (Q in cfs), and its design is representative of modern practice. The entire series of Grand Coulee model pumps was tested in the Hydraulic Machinery Laboratory and thus there is much detailed information available on the over-all performance of the pumping unit (15). Fig. 4 is a scale drawing of the impeller and presents its principal dimensions. The shroud curvature, the discharge and inlet vane angles, and the vane length were modeled to scale directly from the Grand Coulee design. However, the slight curvature or spooning of the vane in the eye was omitted and the vane was terminated along a straight line in the meridional projection. Although this alteration speeded production of the test impeller, it is not a limitation of the manufacturing technique; exact curvature of the prototype can be duplicated in the model if tests indicate the necessity. The discharge-vane tips were left blunt for the present tests.

A FREE IMPELLER

It was required that the flow through the rotating impeller be independent of external effects. The flow was delivered to the impeller eye by a nozzle which matched the eye diameter exactly, and which was designed to give a uniform velocity profile at that section (14). The impeller was mounted directly above the nozzle and was rotated about a vertical axis. When using the centerless impeller mount, Fig. 2, the large journal bearing located between the impeller and the nozzle effects the necessary seal, whereas in the setup for the head-capacity measurements a ring of $1/8$ -in.-sq packing seated in a groove in the nozzle bears against the impeller and seals the suction side against leakage. It was intended originally that the impeller should be operated with a free atmospheric discharge, Fig. 5; however, as the capacity is reduced, thus lowering the static pressure in the eye, a point of instability is reached; the water breaks away from the top shroud and air flashes back into the impeller. This results in operating with passages partially filled, Fig. 6. Operating the impeller at extremely low speeds will avoid this difficulty, but the magnitude of the head generated and the flow rate are reduced correspondingly, and measurements become exceedingly difficult.

FIG. 3 EQUIPMENT FOR DETERMINING HEAD-CAPACITY CHARACTERISTICS

FIG. 4 PRINCIPAL DIMENSIONS OF TEST IMPELLER

FIG. 5 AN IMPELLER DISCHARGING INTO A FREE BODY OF WATER AT HIGH CAPACITY; FULL PASSAGES

A symmetrical stationary collector about the discharge of the impeller furnished a satisfactory solution to the problem. The collector matches the impeller width at the periphery of the impeller and reduces to a smaller opening at its outer rim. A cylindrical weir is used to vary this opening and thus maintain a sufficiently high pressure in the collector and impeller to prevent flashback. The clearances between the impeller and the collector are close-running. Qualitative and quantitative studies of the flow pattern at the periphery of the impeller in the zone indicated in Fig. 4 were made with the impeller discharging freely, and also into the collector. Those showed that the latter had no perceptible effect on the pattern of flow in that zone. With the exception of the flow in the boundary layer at the pe-

FIG. 6 AN IMPELLER DISCHARGING INTO A FREE BODY OF WATER AT LOW CAPACITY; PARTIALLY FILLED PASSAGES

riphery, it is believed that the flow pattern at the discharge and throughout the entire impeller is unaffected. The test unit so arranged is considered to be hydraulically independent of the test setup and hence is referred to as a "free impeller."

FLOW OBSERVATION

Instrumentation and Procedure. A three-dimensional photographic technique was used in making the quantitative flow studies. Thus the problems of instrument response and obstruction to the flow presented by mechanical methods were eliminated. However, photographic techniques required that the test passages be transparent and that suitable photographically identifiable particles be present in the stream. A mixture of dibutyl phthalate and kerosene proportioned to give a specific gravity equal to that of the water,⁴ colored white and observed against a black background, was found to be satisfactory. This mixture is immiscible with water and, when injected into the flow, forms small globules which retain their identity and, when illuminated properly, are photographically discernible. Unlike the more common carbon tetrachloride-benzene solution, the mixture is not injurious to lucite. The tracers were released from a series of small capillary tubes arranged in the throat of

⁴ Equality was satisfactory when globules remained suspended in a sample of the water.

the suction nozzle. Neglecting the minor surface-tension effect, the small tracers formed, $1/32$ to $1/16$ in. diam, may be considered to follow the same flow paths as the water itself.

The tracer paths were recorded with a stereoscopic camera. The stereoscopic technique was necessary to establish the axial position or third dimension of the tracers in the passages. In Fig. 2 is shown the camera located above the periphery of the test impeller. A series of exposures were made on each plate with a controlled burst of flashes of a high-speed multiflash lamp. When the flash rate was matched properly with the impeller speed, the familiar golf-ball-type pictures resulted, Fig. 7. In this manner a number of positions of a tracer were recorded. To determine the tracer velocity, the stereophotographic images were projected back into space through the same lens system, that is, the camera was used as the projector and the space positions of the tracers at each interval of time were located. In this manner the angular, radial, and axial position of the center of each tracer group, the inclination of the group to the tangent, and the displacement of the tracers within the group were obtained. Knowing the time interval, the average velocity of each group was calculated. The shaded peripheral zone in Fig. 4 indicates the region covered by the analysis. The centers of all tracer groups fell within this zone.

The test impeller was operated at 150 rpm and a capacity of 0.293 cfs. At this capacity it was possible to operate the impeller both with and without the collector and hence make the comparative studies mentioned previously. The unit capacity for this operating point is 0.165, Fig. 11. Referred to the Grand Coulee prototype performance, this represents approximately a capacity 40 per cent above the maximum efficiency point and approximately coincides with the upper operating limit of that installation.

Discussion of Results. Figs. 8 and 9 present the results of the tracer studies. The plotted points were all obtained from tracer groups selected at random, the only requirement being that they be within the zone under observation.

The wide scatter of the data is most interesting. At first it might be thought to be experimental error. However, a variation of ± 50 per cent cannot be attributed to experimental errors which did not exceed ± 2 per cent. The second explanation that might be proposed is that the scatter was caused in part by the inclusion of data at various impeller radii and depths within the zone. No correlation between these factors has been observed and hence this contention is not supported by experimental evidence. The scatter could be attributed to any asymmetry existing in the flow through the impeller. However, tracer data were recorded in one specific channel and also in channels at random,

and no asymmetry could be detected. It is possible that large-scale turbulence, present in the incoming flow, might be the source of this dispersion of data. Dyestreak studies have been made in the impeller approach over a wide range of capacities. Large-scale turbulence was not observed until the dye streaks came into close proximity with the impeller passages. It is concluded that the point scatter is due to large-scale turbulence which develops within the impeller passages.

It is interesting to note the increase in the scatter in the region near the trailing edge of the vane which strongly suggests an unstable flow condition. However, although an instability has been noticed in other photographic studies recently completed, a large rolling eddy has not been observed. The scarcity of points close to the trailing edge of the vane is a limitation imposed by the photographic method employed. When a series of exposures are made on one plate, the vane images obscure that area. Stereoscopic high-speed motion pictures overcome this difficulty.

The pronounced dips at mid-passage of the radial velocity C_{m2} , the relative discharge angle β_2 , and the absolute discharge angle α_2 are the most striking features of the data. The decrease in β_2 is to be expected from theory. Likewise, theoretical considerations show that C_{m2} , β_2 , and α_2 must each be of equal magnitude at opposite sides of the vane passage, and this point is verified.

However, the C_{m2} profile is not yet substantiated by theory. Although a three-dimensional analytical solution of the problem is not available, the analysis of a two-dimensional straight radial-vane impeller indicates that, for that special case C_{m2} varies almost sinusoidally about a uniform average through-flow, being least near the leading edge of the vane and greatest near the trailing edge. The present data do not show this trend to exist in a modern three-dimensional impeller. The α_2 variation must necessarily follow the trend indicated, once C_{m2} and β_2 are established.

The obvious dip present in the other plots is noticeably absent in the C_{u2} data. The points suggest that the time-average specific energy about the periphery of an impeller is constant.

The horizontal dotted lines represent values of C_{m2} , C_{u2} , β_2 , and α_2 based upon the Euler infinite-vane theory, namely, the relative discharge flow angle β_2 equals the vane angle, and is everywhere constant, and C_{m2} is constant about the periphery. It is interesting to note that the position of this line with respect to the averages of the test data is in agreement with theoretical deductions. The Euler line must represent the average radial velocity, whereas it should lie above the mean β_2 and C_{u2} and below the mean α_2 .

The instantaneous absolute streamlines pictured in Fig. 10 were sketched from a large number of data prints. The streamlines are spaced at random and hence represent flow direction

FIG. 10 INSTANTANEOUS ABSOLUTE STREAMLINES AT DISCHARGE; RANDOM SPACING

only. It is interesting to note that in the region following the vane there is no evidence of backflow.

DETERMINATION OF HEAD-CAPACITY CHARACTERISTICS

Instrumentation. The inevitable losses involved in the use of a measuring point at any distance from the impeller made it desirable to use total head tubes close to the inlet and outlet to determine the energy of the inflow and outflow from the test impeller. Although there is some doubt as to the correct reference pressure at the inlet, considerations of symmetry indicate that the total head at some point on the center line of the suction nozzle seemed to be a desirable location at which to measure the total head of the incoming flow. A total-head tube directed upstream was located at the inlet to the pump impeller at a point $7/8$ in. below the plane of the intersections of the vane leading edges with the suction shroud. The total-head tube at the outlet was mounted on a rotatable mount and was retractable through a sleeve set at right angles to the axis of rotation. By these means the inlet to the total-head tube could be set at any predetermined distance from the impeller, and its axis could be aligned with the approaching flow. The direction of the flow at the nose of the total-head tube was determined by a probe carrying a fine thread.

Since it has not been possible to obtain a pressure gage with an accuracy and frequency response sufficient to follow in detail the variations in total head, a damped water-column manometer connected directly to the metal total-head tube was used. The air side of the manometer was connected to the air space of a waterpot. The water side of the waterpot was supplied by the total-head tube at the inlet to the impeller; thus the differential head across the runner could be read directly. By adjusting the height of the water level in the pot a large range in head could be covered without great variations in the height of the water level in the manometer tube, Fig. 3.

The question always arises in applications where the measured total head fluctuates, as to the meaning of the reading obtained by the manometer. Experiments were made to determine the influence of the damping imposed on the measuring head, and it was found that a large degree of damping gave steadier readings which were fully consistent with the mean readings obtained with less damping. Since the total-head tube measures a fluctuating energy level directly, and since speed and flow control were of

such quality that the fluctuations could be considered a steady-state condition, a viscously damped system should read the true average total head.

Variation of Total Head Across Outlet. Since the flow through a radial-flow pump involves essentially a change of direction from axial to radial, it was of interest to determine the variation in total head between the lowermost streamline that emerges at the suction or lower shroud and the uppermost streamline that emerges at the back or upper shroud. This is particularly interesting in view of the velocity field observed photographically and discussed previously. A location was chosen for the total-head tube $1/16$ in. distant from the periphery of the impeller. At this location the total-head tube was aligned with the mean streamline and traversed vertically across the width of the impeller. At the chosen flow rates it was found that the energy of the lowermost streamline was approximately 5 per cent greater than the energy of the uppermost streamline. On the basis of these observations a location was chosen halfway between the two shrouds at the outlet for the subsequent work reported here.

Influence of Prerotation on Accuracy of Observations. Experimental work on complete pumps has shown that the flow conditions in the inlet pipe are in many cases highly complex. This requires that justification be provided for measuring the inlet total head with the total-head tube close to the impeller at the center line of the suction nozzle. This was done in the following manner:

The outlet total-head tube was set at $1/16$ in. from the periphery of the impeller at mid-width, and the total head change between the inlet and the outlet was recorded for a large range of flow rates. A typical run is shown in Fig. 11 which is a dimensionless head-capacity characteristic for the test impeller. Since it is reasonable to suppose that the inlet effects, if any, must decrease in intensity as one recedes further from the disturbing influence, other runs were made using the piezometer taps located after the inlet straightening vanes which are some distance upstream from the impeller inlet and guarantee a smooth velocity profile in the approach pipe.

The results of these measurements are plotted in Fig. 11, including the necessary corrections for approach-velocity head, but omitting the small loss due to the friction of the finite length of

FIG. 11 DIMENSIONLESS HEAD-CAPACITY CHARACTERISTICS OF TEST IMPELLER

pipe between the piezometer taps and the impeller eye. This latter correction has not been applied to the typical run shown in Fig. 11 and would improve the agreement at the higher values of dimensionless capacity where its influence is appreciable.

It should be observed that the points plot along the same line as the points determined using the total-head tube in the inlet. This is believed to indicate that in this installation the backflows which may exist do not affect the accuracy of the total-head tube in the eye. Since total head is the measure of the energy of the fluid at the point of measurement, it seems that there has been no energy supplied by the pump to the incoming fluid at the measuring point. Visual observations with dye introduced at the eye indicate that the disturbances in the eye are localized close to the vane leading edges.

Impeller Characteristics. The type of observation discussed in the previous paragraphs may be used to study some of the detailed qualities of an impeller. Near the point of zero head, the head-capacity curve shown on the unit plot in Fig. 11 is closely linear. In the range of maximum efficiency of the prototype impeller, the linearity has disappeared and the characteristic turns smoothly without discontinuities. At a value of $C_{m2}/u_2 = 0.075$, the smooth trend of the characteristic is broken, and in this region a scatter of points was obtained which indicate that the operation of the impeller is unstable. The region of instability is indicated by the dip in the characteristic. After this region is passed, unique values are again obtained for the dimensionless head.

As a matter of interest, the unit characteristic of the prototype impeller is plotted in Fig. 11 and is marked "GC-7 Vanes." The zone of discontinuity for this impeller is marked by two vertical lines which fall in practical coincidence with the zone of discontinuity of the six-vane test impeller. Work has not yet been completed on the five-vane impeller based on the same prototype to enable definite conclusions to be drawn from this coincidence. It indicates, however, that the position of the unstable range may depend primarily on the vane shape for impellers having sufficient vane overlap.

Prerotation. It was observed very early in the experimental work that the impeller developed zero head at a flow which still showed a positive tangential component of absolute velocity at the outlet. This has been verified very carefully both by observations of the absolute flow and by measurements with the total-head tube at the outlet. Since this condition requires that the flow enter the eye with a positive prerotation, there seems to be no doubt that such a phenomenon occurs, although visual evidence indicates that this is a local effect. The absolute angle of emergence of the flow at the periphery is quite acute and cannot be attributed to experimental error in the measurement of the direction of the outflow.

Variation of Characteristic With Position of Outlet Total-Head Measurement. The type of total-head tube used in these investigations was not sensitive to yaw of the flow over the angles encountered at the outlet of the impeller except, perhaps, in the neighborhood of the vane tips. The vane tips were left wide and unsharpened. When runs are made with the Pitot head further from the outlet than has been used in the previous experiments, lower total heads are measured. Fig. 11 shows a few points taken at $1/8$ in. from the periphery and $1/4$ in. from the periphery, and they define a characteristic lower than the one obtained with the measuring point $1/16$ in. from the periphery. On the basis of present evidence it is not possible to explain this shift. Variations in instrumentation have not caused any noticeable difference in this phenomenon, and it cannot reasonably be ascribed to losses due to mixing or to the losses in the rudimentary collector ring.

The lowest curve in Fig. 11 was obtained with the measuring

point distant from the periphery of the impeller before the behavior of the total head near the impeller was noticed. This curve represents a minimum and undoubtedly contains losses due to the collector ring.

The head-capacity line, based on an infinite number of vanes and the outlet vane angle, is also shown in Fig. 11, as well as two lines for six and seven vanes, based on Busemann's (16) solution of the two-dimensional radial-flow impeller with a finite number of logarithmic spiral vanes. The displacement between the GC-7 vane characteristic and the Busemann line for seven vanes indicates that the characteristic for the test impeller is too high in relation to its corresponding Busemann line for six vanes. This indicates that the experimental data based on a measuring point very close to the outlet contain a systematic error. However, this discrepancy does not affect the experimental procedure when general characteristics of the runner are being investigated and efficiency determinations are not involved.

Influence of Collector Ring. The collector ring used in the determination of the characteristic consists of two parallel plates set apart the width of the outlet which were necessary to prevent air from striking back from the free surface. In order to throttle the outflow, one cylindrical ring was attached to the circumference of each collector-ring plate, and these could be set apart a determined amount. A systematic series of runs showed that in the range of operation there was no influence of the throttle gap on the measurements.

Affinity Relation. The data presented in Fig. 11 were obtained at a rotative speed of 225 rpm; at this speed the maximum head reading was 2.06 ft. This permitted a high accuracy of measurement of the differential head except near zero head. Flow measurements were accurate to better than 1 per cent at all flows.

With this accuracy available, another series of runs were made at 150 rpm to detect, if possible, the influence of rotative speed on the characteristic which could be significant at the low speeds used in these tests. The correspondence between the dimensionless head-capacity plots for the 225-rpm series and the 150-rpm series was complete within the accuracy of the experimental data.

Discussion

A. J. ACOSTA.⁵ The need for a series of investigations on the individual elements of a hydraulic machine has been recognized for some time. Due to the somewhat inconclusive experimental results to date, it has been impossible to evaluate the separate effects of the components of a hydraulic machine. For that reason, the interpretation of observed phenomena and correlation with any real or perfect-fluid theory has lagged. Accordingly, the study of an impeller or volute, wherein its effects are isolated, should enable the laboratory to perform for the first time definitive tests as to the nature of flow in hydraulic machinery.

In reference to the plots of C_{m2} and C_{a2} (Fig. 8 of the paper), the authors state that there is as yet no theoretical justification for their behavior. The writer has had occasion to make an analysis of the flow of an inviscid incompressible fluid in a two-dimensional rotating-vane system. Inasmuch as an "ideal" solution offers possibilities of interpreting test data, it seems pertinent to present it now. The geometry of the chosen idealized impeller consists of eight logarithmic spiral vanes with a characteristic angle of 45 deg and a radius ratio of 0.5. The analysis involves the numerical evaluation of the differential equation governing the flow subject to appropriate boundary conditions. In the case considered, an absolute co-ordinate system (stationary with respect to the inertial reference frame) was chosen so that the differential equation to be solved is Laplace's equation in two dimensions, i.e., $\partial^2 U / \partial x^2 + \partial^2 U / \partial y^2 = 0$ where U is either the stream function or velocity potential for the flow. The boundary conditions are: (a) there is no flow through the vanes; (b) there is no flow around the tip of the vanes at exit. This latter condition is merely a statement of the Kutta-Joukowski principle for the flow around lifting surfaces. The vanes are taken to be infinitely thin, although this condition is not necessary for the solution of the problem. Finally, we require that the velocity diminish to zero at an infinitely great distance from the impeller. Then, to within an additive constant, the stream function and velocity potential for the flow are uniquely defined, and the velocities in the field may be computed from either. The flow rate through the impeller is accounted for by placing a line source at the origin. Rather than compute a number of solutions

for separate flow rates only two need be found, since the resulting velocity field within the impeller can be resolved into two parts, namely, (a) the flow due to the rotation of the vanes without any net through-flow (corresponding to shutoff head); (b) the flow from a source through a set of radially disposed stationary guide vanes. Solutions of this latter sort are available.⁶ Combined with the present work which is only for zero flow rate, the flow for any operating point on the head flow-rate diagram may be obtained by taking a linear combination of (a) and (b):

The solution itself was effected by the so-called "relaxation" method.⁷ Briefly, the method for solving Laplace's equation is as follows: The value of the function in the region of interest is approximately determined at the intersecting points of a rectangular grid. Then, to the first order, the finite-difference equation representing Laplace's equation is $\psi_1 + \psi_2 + \psi_3 + \psi_4 - 4\psi_0 = 0$, where ψ_1 to ψ_4 are the values of the function at the nearest four intersecting points to the point 0. This equation is satisfied at each point in the region by a trial-and-error process. Ways in which this is readily accomplished are discussed by Southwell.⁷

The solution was carried out by the method described, and from it the variation of the radial velocity across the impeller-exit section was determined and is shown in the accompanying diagram, Fig. 12. The value of the unit head at zero flow rate is 0.79, which is the same as that given by Busemann's theory⁸ for logarithmic vanes. Although it is unfortunate that the dimensions of the impeller chosen for analysis are somewhat different from those of the test impeller, the order of magnitude of the velocities and the general features of the flow will be the same.

Comparing Fig. 8 of the paper with Fig. 12 computed by the writer, one sees that the dip in the radial-velocity distribution is substantiated by theory. For logarithmic vanes of the angle and radius ratio used in the analysis and for the test impeller, the radial-velocity variation at the impeller exit is nearly unaffected by the flow rate; so we are justified in comparing the variation at zero flow rate with that of the experiment. The range of variation seen in Fig. 8 is about a radial velocity of 1 fps, or in a dimensionless form it is 0.15, arrived at by dividing

FIG. 12 PLOT OF RATIO OF RADIAL VELOCITY TO PERIPHERAL VELOCITY AT EXIT SECTION COMPUTED FOR A TWO-DIMENSIONAL IMPELLER WITH EIGHT LOGARITHMIC SPIRAL BLADES HAVING A VANE ANGLE OF 45 DEG AND A RADIUS RATIO OF 0.5 FOR ZERO FLOW RATE

by the peripheral velocity. The maximum variation computed from the two-dimensional ideal fluid case is about $\Delta C_{m2} / U_2 = 0.14$. The only noticeable departure in general trend between the two is found near the leading surface, where it is seen that the area of positive C_{m2} is much less for the computed case than for the test results. This is, however, the trend one would expect as the vane angle becomes steeper.

As the authors mentioned, the dip apparent in the C_{m2} , β_2 , and

α_2 is not evident in the C_{u2} (absolute tangential velocity at exit) plot. For the special case analyzed, the range of variation of C_{u2} compared with the mean value was found to be 18 per cent, 12.5 per cent being positive occurring at the boundary on the vane tip. It is, then, not surprising that a variation of this order of magnitude should not be observed on the authors' plot, in view of the large point scatter.

The general trend of the data presented is seen to follow that predicted by two-dimensional perfect-fluid theory, a surprising fact considering the high level of turbulence present in the flow. However, the limitations of perfect-fluid theory for flows of this sort are as yet unknown. The writer is interested in this problem and hopes to see it explored further.

This work was supported by the Office of Naval Research.

AUTHORS' CLOSURE

The authors thank Mr. Acosta for his discussion and consider it a valuable contribution. More complete and detailed studies made on a series of impellers since the completion of the paper indicate that in the region of the design point, the total head generated by the impeller matches rather well (within 8 per cent) the ideal Busemann value, and also that the head-capacity curve of the free impeller follows very closely the ideal straight-line relationship. In this region prerotation is nil; there is no separation within the passages and the discharge flow pattern is primarily two-dimensional. Hence, in this region, the two principal parameters present in the real fluid case but omitted in the ideal case

are viscosity, μ , and the temporal velocity variations $\frac{\partial v}{\partial t}$. If through continued research the effects of these quantities on the ideal solution can be determined, an extremely powerful tool would be made available to the researcher and designer.

Unfortunately, the whole picture is not quite as simple as might be inferred. At off-design points, observations show that the flow separates from the channel walls and follows unknown and indeterminate boundaries. Cross flows develop and the discharge flow pattern does not remain two-dimensional. These elements impose serious limitations on the potential approach in the very regions where its use to predict off-design point performance would be most desirable. On top of all this, it must be remembered that the ideal situation applies only to a free impeller; an impeller operating in an infinite fluid medium with stationary boundaries only at infinity. Tests have shown that the characteristics of the complete pump, consisting of impeller and case, differ widely from those of the free impeller at all points except the design point. Hence the effect of the volute must be considered and incorporated in the final solution.

It is not meant to imply by these remarks that the potential solution is considered either impractical or impossible. The intent of the authors is to point out the long road ahead and the vast areas yet to be explored, and to underline the statement that at these early stages of the work it is most gratifying to find a good correlation between potential theory and experiment in some parts of the field.

The Flow Through Centrifugal Compressors and Pumps

By H. E. SHEETS,¹ AKRON, OHIO

The flow through centrifugal compressors and pumps is a three-dimensional flow problem and is of such a complex nature that an exact solution is not obtainable. The literature (1, 2)³ shows the differential equations which the flow through an impeller must follow. An approximate solution to these equations is found by means of certain assumptions which are possible for impellers within a limited range of specific speeds. The solution gives the approximate velocity and pressure distribution in the impeller passages. The knowledge of the velocity distribution is used to analyze the phenomena of pulsation and blade stalling. The method has also been used in mixed-flow compressors and radial- and mixed-flow turbines. The application of this method for two impellers and test data are presented.

NOMENCLATURE

The following nomenclature is used in the paper:

- a = distance between 2 blades normal to flow lines
- c = absolute velocity
- f = area
- l = blade length
- m = mass
- p = pressure
- r = impeller radius
- t = blade pitch
- u = tip speed of impeller
- w = relative velocity
- z = blade number
- n_s = specific speed
- Q = total flow
- R = blade radius of curvature
- β = blade angle
- $\gamma = 1/v$ = specific weight
- ω = angular velocity
- σ = blade solidity

Indexes:

- 2 = impeller exit
- 1 = impeller inlet
- * = arbitrary point in impeller passage

Other symbols will be defined in the text.

DERIVATION OF APPROXIMATE SOLUTION—BLADE CENTER SECTION

The approximate solution of the flow problem considers the impeller-blade passage as a rotating channel for the center section. The first step is the determination of the approximate

velocity distribution in this center section, and then the solutions for the exit and inlet of the blade passage are added. The result gives the nonuniform velocity distribution throughout the entire blade passage.

This method is therefore limited to blade passages which are long enough to permit a division in three sections, and it is necessary that the center section, treated as a rotating channel, extend at least over a limited length. Therefore the proposed method is limited to a range of blade solidity

$$\sigma = \frac{l}{t} = \frac{z}{2\pi \sin \beta} \log_e \frac{r_2}{r_1} \geq 1.3 \dots \dots \dots [1]$$

or approximately

$$\sigma' = \frac{l}{l_2} = \frac{lz}{2\pi r_2} \geq 1.2 \dots \dots \dots [1a]$$

This definition for blade solidity is given in reference (3).

Fig. 1 shows a schematic drawing of an impeller. For two-dimensional flow the blade width has a constant value, $b = \text{const.}$ Considering the relative flow in the center section of the rotating channel in Fig. 1, we apply to the particle of mass dm the com-

FIG. 1 FORCES IN A ROTATING CHANNEL WITH BACKWARD CURVED VANES

plementary forces $dm \, r\omega^2$ and $dm \, 2w\omega$. The normal acceleration toward the center of curvature is w^2/R , and we have the equation of motion

$$dm \frac{w^2}{R} = df(p - p^*) + dm \, 2w\omega - dm \, r\omega^2 \cos \beta \dots \dots [2]$$

for backward-curved vanes.

Since

$$dm = df \, dn \frac{\gamma}{g} = df \, dn \frac{1}{v\gamma}$$

and

$$dp = p - p^*$$

and according to Fig. 1, taking dn positive from the low-velocity side of the blade to the high velocity side

$$dr = dn \cos \beta$$

we get

$$\frac{w^2}{R} = v g \frac{dp}{dn} + 2w\omega - r\omega^2 \frac{dr}{dn} \quad [3]$$

The energy equation of a streamline is

$$\frac{w^2 - w^{*2}}{2g} = - \int_p^p v dp + \frac{u^2 - u^{*2}}{2g} \quad [4]$$

For infinitely close-lying points it is with $dw = w - w^*$

$$\frac{w dw}{g} = -v dp + r\omega^2 \frac{dr}{g} \quad [5]$$

Comparing Equations [3] and [5], we get

$$\frac{w}{R} + \frac{dw}{dn} - 2\omega = 0 \quad [6]$$

for backward-curved vanes. For forward-curved vanes we get

$$\frac{w}{R} + \frac{dw}{dn} + 2\omega = 0 \quad [6a]$$

For the purpose of our approximate solution we make the assumption that the radius of curvature of the streamlines is approximately constant for each line orthogonal to the flow lines. The radius of curvature may vary from vane inlet to exit. This assumption means

$$R = \text{const.} \quad [7]$$

For the center section, Equation [7] is a good approximation, and for straight-bladed impellers it is correct.

Then Equation [6] becomes

$$\frac{dn}{R} = \frac{dw}{2\omega R - w} \quad [8]$$

For $n = 0$ the minimum velocity at the channel wall is designated as w' and the solution for Equation [8] becomes

$$w = (w' - 2\omega R)e^{-\frac{n}{R}} + 2\omega R \quad [9]$$

Developing the exponential function into a series and omitting third and higher powers of n/R we get

$$w = w' + \left(2\omega R - \frac{n}{R} w'\right) \left(1 - \frac{n}{2R}\right) \quad [10]$$

Defining the mean velocity as

$$w_m = \frac{Q}{ab} = \frac{\int_a^b w b dn}{ab} \quad [11]$$

a and b are the channel width and height, respectively.

Substitution of Equation [10] in [11] and some transformation give us the following for the extreme local velocities at the channel wall:

Minimum velocity for $n = 0$

$$w' = w_m \left[1 + \frac{a \left(1 - \frac{a}{3R}\right)}{2R - a \left(1 - \frac{a}{3R}\right)} \right] - a\omega \left[1 - \frac{a}{3R} + \frac{a \left(1 - \frac{a}{3R}\right)^2}{2R - a \left(1 - \frac{a}{3R}\right)} \right] \quad [12]$$

Maximum velocity for $n = a$

$$w'' = w_m \left[1 - \frac{a \left(1 - \frac{2a}{3R}\right)}{2R - a \left(1 - \frac{a}{3R}\right)} \right] + a\omega \left[1 - \frac{2a}{3R} + \frac{a \left(1 - \frac{a}{3R}\right) \left(1 - \frac{2a}{3R}\right)}{2R - a \left(1 - \frac{a}{3R}\right)} \right] \quad [13]$$

For straight blades $R = \infty$ these equations become

$$w'_s = w_m - a\omega \quad [12s]$$

$$w''_s = w_m + a\omega \quad [13s]$$

For forward-curved blades we get similarly

$$w' = w_m \left[1 - \frac{a \left(1 - \frac{2a}{3R}\right)}{2R - a \left(1 - \frac{a}{3R}\right)} \right] - a\omega \left[1 - \frac{2a}{3R} + \frac{a \left(1 - \frac{a}{3R}\right) \left(1 - \frac{2a}{3R}\right)}{2R - a \left(1 - \frac{a}{3R}\right)} \right] \quad [12a]$$

$$w'' = w_m \left[1 + \frac{a \left(1 - \frac{a}{3R}\right)}{2R - a \left(1 - \frac{a}{3R}\right)} \right] + a\omega \left[1 - \frac{a}{3R} + \frac{a \left(1 - \frac{a}{3R}\right)^2}{2R - a \left(1 - \frac{a}{3R}\right)} \right] \quad [13a]$$

The flow through the impeller can be divided into two parts, the "through flow" associated with w_m and the "displacement flow" associated with ω . With $w_m = 0$ we get in Equations [12] and [13] the values for the displacement flow alone.

BLADE EXIT

It is known that the relative flow through a centrifugal impeller can be expressed by a relative flow function as a sum

$$\psi = \psi_1 + \psi_2 + \psi_3$$

where

ψ_1 = flow function for through flow

ψ_2 = flow function for displacement flow

ψ_3 = flow function for circulation flow

The flow is infinite and neutralized by torsion solutions shapes

To determine that the end of the flow line between the line and the distribution of the flow line where the flow is equal to the flow line

The simple triangle from the triangle proximal of the polygon

For the straight line according to the

The channel distance is taken to the line and the line is we have separation

The axial location [12] a channel

For the frequency axial w_m element mine At case shape n ag side [2] to

The flow functions ψ_1 and ψ_2 must be of such a nature that the infinite velocity at the inlet edge caused by the through flow is neutralized. Stodola (1) has shown that the solutions of the flow function ψ_2 and ψ_3 can be found by the membrane analogy or by torsional stress analogy. In the literature (4, 5) are published solutions for the stress analogy for a large number of simple shapes.

To determine the shape of the blade-exit channel, we assume that the end effects extend a distance $t_2/2 = (D_2/2z)\pi$ from the end of the blade inward. This distance is taken along the mean flow line. A line orthogonal to the flow lines is the separation line between the center section and the blade exit. The velocity distribution up to the separation line is known according to Equations [12] and [13]. We have now to determine the variation of the velocities from the separation line to the blade exit, where the velocity on both sides of the blade must be uniform and equal to the through-flow velocity.

The shape of the blade exit thus determined is usually very simple so that the variation of velocity can be taken directly from the stress analogy for such shapes as sector of a circle, triangle, and many others. For more complex shapes, an approximate solution can be found according to the energy method of the torsional problem as proposed by Ritz and Trefftz (4). With this method the velocity distribution can be found for any polygon-shaped channel exit.

For an exit channel of nearly rectangular shape, the results of the stress analogy (5) show a velocity variation approximately according to a parabola from a known value at the separation line of the center section to zero at the blade exit.

BLADE INLET

The blade inlet can be treated like the blade exit. Therefore it becomes necessary to determine the shape of the blade-inlet channel. In this case we assume that inlet effects extend to a distance $t_1 = D_1\pi/z$ from the blade inlet inward. This distance is taken along the mean flow line. A potential line orthogonal to the flow lines is the separation line between the center section and the blade inlet. The velocity distribution at the separation line is known according to Equations [12] and [13]. In this case we have to determine the velocity distribution from the stagnation point of the blade at the inlet to the known values at the separation line with the center section.

The blade-inlet velocity distribution can be determined according to the method of Betz (6, 7), and Akeret (8) for the axial inducer-type impeller.

It is thus possible by starting with the calculation of the velocity distribution in the center section, according to Equations [12] and [13], to find the velocity distribution in the entire blade channel.

THREE-DIMENSIONAL FLOW

For three-dimensional flow the blade height is not constant and usually decreases from impeller inlet to impeller outlet. Frequently the flow turns in the vicinity of the impeller inlet from axial to radial direction. This means that the mean velocity w_m changes as a function of the blade height and must be determined.

At first we determine the absolute velocity c_m for the hypothetical case of the fluid flowing through a stationary impeller of identical shape. We designate the radius of curvature with ρ , and taking n again from the low-velocity side of the flow, i.e., the convex side in this case, we get from considerations similar to Equations [2] to [6]

$$\frac{dn}{\rho} - \frac{dw}{w} = 0 \dots \dots \dots [14]$$

A graphical solution for the velocity distribution according to Equation [14] can be found according to the method of Flugel (1).

Another method which permits direct calculation of the velocity distribution is possible if the impeller contours can be approximated by two hyperbolas following the equation

$$r^2 x = C \dots \dots \dots [15]$$

Then, the velocity calculated according to the basic equation from Durand (9) is

$$c_m = \frac{C}{2\pi} \sqrt{(2x)^2 + r^2} \dots \dots \dots [16]$$

According to either method, the absolute velocity c_m is determined for the mean streamline as well as for the inner and outer contours of the impeller, $c_{m,i}$ and $c_{m,o}$, respectively.

The relative velocity is

$$w_m = \frac{c_m}{\sin \beta} \dots \dots \dots [17]$$

where β is the local blade angle at the location of c_m . Equation [17] assumes that the mean relative velocity follows the blade contour, and this assumption is justified for the center section or rotating channel of the impeller. For impellers within the specified solidity range, Equation [17] gives also a good approximation for inlet and exit of the blade channel.

For impellers with large inducers, Equation [17] must be replaced for the blade-inlet condition by more accurate equations following the theory of axial machines (3).

Thus $w_{m,i}$ and $w_{m,o}$ can be determined for the inner and outer contour of the impeller and these velocities exist at the mean streamline between two blades.

Equation [17] cannot be used when large secondary flows occur, such as those caused by blade stalling or the impeller operating under considerably larger or smaller flow than design point.

COMPRESSIBILITY AND FRICTION

The effect of compressibility is taken into consideration by calculating the area of the impeller-flow channel for an arbitrary number of stations along the mean flow line. The velocity w_m^* is calculated from the total flow on the basis of the known area and an estimated compressibility. Later w_m^* is recalculated according to correct compressibility. The enthalpy increase from the conditions at the inlet to the compressor to an arbitrary station inside the impeller is

$$H^* - H_0 = \frac{w^{*2} - w_0^2}{2g} + \frac{w_{m1}^2 - w_{m2}^2}{2g} - \frac{c_1^2 - c_0^2}{2g} \dots [18]$$

The first two terms in Equation [18] define the enthalpy increase in the impeller, and the last term defines the inlet depression caused by the acceleration of flow from the known conditions to the impeller inlet.

Part of this total enthalpy increase is transformed into pressure and the other part into heat. The amount of enthalpy transformed into pressure is defined as

$$\Delta H_{AD} = \eta_e (H^* - H_0) = \frac{k}{k-1} RT_0 \left[\left(\frac{p^*}{p_0} \right)^{\frac{k-1}{k}} - 1 \right] \dots [19]$$

where η_e is the impeller channel efficiency, which is a function of the channel Reynolds number, turbulence, friction coefficient, and boundary-layer condition; η_e must be assumed on the basis of experience.

Equation [19] permits the calculation of the pressure rise $(p^*/p_0)_{AD}$. The temperature increase is

$$\frac{T^*}{T_0} = 1 + \frac{H^* - H_0}{c_p T_0 J} \quad [20]$$

and the volume change becomes

$$\frac{V^*}{V_0} = \frac{T^*}{T_0} \left(\frac{p_0}{p^*} \right)_{AD} \quad [21]$$

The correct volumes and velocities can be calculated according to Equations [18] to [21], and the original estimate of the compressibility is replaced by the accurate value of Equation [21]. Thus the correct values of the velocity w_m in Equations [12] and [13] are calculated. Then the following velocities are calculated, at first on the basis of incompressible flow, w_m ; w_{m0} along the inner and outer contour of the impeller and the local velocities w' , w'' ; w'_1 , w'_2 , w''_1 , and w''_2 , according to Equations [12] and [13]. If any of the foregoing velocities vary greatly from its corresponding value of w_m , the compressibility correction is calculated in the same manner.

This analysis permits calculation of the impeller-velocity distribution and gives a complete map of the velocity values for the three-dimensional compressible flow through the impeller.

The velocity distribution shall be represented as a function of the blade length and, for dimensionless representation, the values shall be divided by tip speed and impeller-tip radius, respectively.

ACCURACY OF APPROXIMATE SOLUTION

For the theoretical case of two-dimensional flow through radial-flow impellers, we can compare the results of the approximate solution with a flow analysis which has been calculated according to the relaxation method by Professor Emmons (10) for two types of impellers. In this report the velocity distribution is determined separately for the through flow and the displacement flow. The two types of impellers, which have been analyzed, are a straight radial-vane, $\beta_2 = 90$ deg, 22-blade unit, and a backward-curved $\beta_2 = 30$ deg logarithmic spiral-blade unit. Both impellers have a radius ratio $r_1/r_2 = 0.333$, constant blade width b , and a solidity of $\sigma = 3.84$.

Fig. 2 compares the velocity distributions of the displacement flow for the straight radial-vane unit. The solid line shows the velocity distribution according to the relaxation method of

FIG. 2 VELOCITY DISTRIBUTION OF DISPLACEMENT FLOW FOR RADIAL-VANED IMPELLER, $z = 22$

FIG. 3 VELOCITY DISTRIBUTION OF DISPLACEMENT FLOW FOR IMPELLER WITH BACKWARD-CURVED VANES, $z = 11$; $\beta_2 = 30$ DEG

Professor Emmons, and the dash line according to the approximate solution of Equations [12] and [13] with $w_m = 0$. A comparison on the basis of the displacement flow will show any discrepancies more clearly because total flow consists of the sum of displacement flow and through flow. Fig. 3 shows the velocity distribution for the displacement flow for the backward-curved unit, again with the solid line and dash line indicating the values of the relaxation method and the approximate solution, respectively. The two results indicate very good agreement for almost the entire blade passage and justify the use of the approximate solution.

We can also calculate the effect of finite blade number on the relative exit velocity. For the range of solidity under consideration this effect may be ascribed to the displacement flow only, and the influence of the circulation flow may be neglected (3). The calculation is identical with the stress or membrane-analogy methods discussed before, except that we calculate this time the velocity distribution along the impeller-exit diameter. This velocity distribution is again taken from the stress analogy. From the velocity distribution we calculate the mean value of this circumferential velocity Δw_u . This is the desired velocity correction for the finite number of blades. For nearly rectangular exit shapes, the velocity distribution is, as before, approximately a parabola, and the maximum velocities are proportionate to the width and height of the shape. The maximum velocity on the sides of the exit shape exists at the separation line between the center section and exit section and is known from the values of Equations [12] and [13] with $w_m = 0$.

The velocity Δw_u has been calculated for the two cases mentioned previously. The values are compared with the values for Δw_u

TABLE 1 RELATIVE VELOCITY CORRECTION

Relative velocity correction	Stodola ^a $\Delta w/w$	Busemann ^b $\Delta w/w$	Emmons $\Delta w/w$	This method $\Delta w/w$
Radial vanes 90 deg, $s = 22$	$0.143 \times w_2$	$0.105 \times w_2$	$0.086 \times w_2$	$0.108 \times w_2$
Backward-curved vanes 30 deg, $s = 11$	$0.143 \times w_2$	$0.137 \times w_2$	$0.136 \times w_2$	$0.137 \times w_2$

$$^a \Delta w/w = \frac{v \sin \beta_2}{s} \times w_2 \quad \text{Reference (1).}$$

$$^b \text{Reference (3).}$$

calculated according to the theories of Stodola, Busemann, and Emmons. Table 1 shows the results.

For the backward-curved impeller the theories of Busemann and Emmons agree with the results of this calculation, and, for the radial-vaned impeller, the results of this calculation agree with the theory of Busemann, but the value is somewhat above that of Emmons.

PRACTICAL APPLICATIONS

The application of the analysis will be shown for two cases. The first case relates to a compressor A which had a very narrow range of operation and pulsation outside this range of operation. An analysis of this impeller was suggested in order to find whether the range of operation could be improved. Fig. 4 shows the velocity distribution for this impeller. The vertical lines indicate the separation between the inlet, the center and exit section of the flow channel. The mean velocity w_m shows a decrease from inlet to exit of the impeller but does not permit any conclusion regarding the stability range of the unit. Backflow or pulsation of an impeller will start if the local velocity on the forward side of the blade becomes zero, and, in this impeller, the local velocity distribution indicates narrow range of operation. In this case the velocity difference $w_m - w'$ is a function of the angular velocity ω and channel width a only, according to Equation [12], with $R = \infty$, and does not change with w_m in the critical region of lowest values of w' on the forward side of the blade. Therefore a reduction in total flow of 13 per cent reduces the mean velocity in the same proportion and results in a value of mean velocity equal to $w_m - w'$ in the critical region; thus making the value of local velocity w' on the forward side zero. Backflow will occur if the flow is reduced 13 per cent.

Another item of importance is the amount of deceleration on either side of the blade per unit length. Too large an amount of deceleration causes high pressure gradients and stalling of the blades. While the velocity-distribution diagram permits predicting pulsation caused by backflow, the stalling of the blades cannot be analyzed quantitatively from the diagram, because stalling is affected by boundary-layer thickness, turbulence, and blade finish. However, on the basis of comparison of similar velocity distributions, experience can be gained indicating which velocity distributions tend to avoid stalling. The large decelerations on both pressure and velocity side of the blade of impeller A indicate a danger of stalling and thick boundary layers even under normal operation.

The second case relates to a compressor which was designed by use of the foregoing velocity-distribution method. The specifications called for a pressure ratio of 3 at 40,000 ft altitude, a wide range of stability, and a certain maximum flow capacity. Since this unit was tested under sea-level conditions, the specifications were recalculated for sea-level conditions as follows:

$$\text{Flow, } Q = 4850 \text{ cfm}$$

$$\text{Pressure ratio, } p = 2.54$$

$$Q_{\text{max}} = 5280 \text{ cfm}$$

$$\text{Speed, } n = 19,600 \text{ rpm}$$

$$n_s = \bar{n} \frac{\sqrt{Q}}{g^{1/4} H^{1/4}} = 0.096$$

In order to get the desired range of stability, the design point

FIG. 4 UNDESIRABLE VELOCITY DISTRIBUTION IMPELLER A
($D_2 = 13.25$ in., $w_1 = 700$ fps, $n_s = 0.110$.)

FIG. 5 IMPELLER B, 14 SHORT VANES, 14 FULL VANES

was chosen 8 per cent below the point of maximum capacity. Fig. 5 shows this compressor. This impeller has 14 full vanes and 14 short vanes. Fig. 6 shows the velocity diagram with regard to the mean relative velocity for this impeller. The various regions of the flow channel are separated by vertical lines.

The mean relative velocity shows decreasing values from inlet to exit, as well as a continuous change in decrease to the smaller

FIG. 6 VELOCITY DISTRIBUTION FOR MEAN FLOW PATH OF IMPELLER B

decelerations at the discharge end. The local velocities indicate the same characteristics on the high-pressure side of the blade, giving the largest decelerations at the blade entrance of the full and half-vanes, respectively. The low-pressure side of the blade shows little change in velocity, except at the discharge end of the blade and at the entrance into the half-vanes. The lowest value of local velocity occurs in a region where $R = \infty$; therefore, according to Equation [12], the velocity difference ($w_m - w'$) is a function of the angular velocity ω and channel width a only. Thus, reducing the through flow 33 per cent results in a value of mean velocity equal to $w_m - w'$ in the critical region, $l = 0.70$, and the value of the local velocity w' becomes zero. This means that backflow has progressed to the center of the blade channel and pulsation will occur. The beginning of pulsation can be analyzed by calculating the velocity distribution for the inner and outer contours of the impeller. From the curve, Fig. 6, it can be seen that this impeller would pulsate without the half-vane at its design flow and that half-vanes permit the extension of the operating range by reducing the value of local velocities.

Fig. 7 shows the velocity distribution of the impeller for the inner contour with the mean value w_{mi} and for the outer contour, mean value w_{mo} . All velocities have been calculated by taking into consideration an approximate value of the boundary-layer thickness. From the local velocity distribution a revised estimate of the stability range can be made. The lowest local velocity occurs on the forward side of the blade near the impeller disk. The critical value is again near the blade exit, $l = 0.70$, because in this region the value of w_{mi} is near its minimum value and $R = \infty$. Thus ($w_{mi} - w_i'$) is independent of w_{mi} , according to Equation [12]. Therefore a reduction of 27 per cent of the design capacity will result in the first local velocity value of $w_i' = 0$ initiating backflow. At a slightly larger reduction, 28 per

cent of design capacity, the local velocity w' also becomes zero in the second critical region at $l = 4.45$ near the inducer exit of the full vanes at the impeller disk. At this flow the local velocity value w' in the critical region near the impeller exit is negative at the impeller disk and backflow progresses toward the center of the flow channel.

The local velocity w'' on the back side of the blade close to the impeller shroud has the maximum value near the inducer inlet. This is the maximum value of velocity in the entire blade channel. An increase of 9 per cent above design capacity will result in the first occurrence of local sound velocity at this location. This analysis, therefore, indicates a total operating range of about 36 per cent.

Fig. 8 shows test data of the performance curve for this compressor at 1100 and 1140 fps tip speed. These performance curves indicate an operating range of 28 per cent from the design point to the beginning of pulsation, and a range of 10 per cent from the design point to maximum capacity, giving a total range of about 38 per cent at which the compressor efficiency is above 70 per cent.

Therefore the performance curve verifies the predicted result of the velocity-distribution curves. The maximum efficiency is above 79 per cent, and it should be remembered that this unit operates at an unusually low specific speed. Due to the instrumentation, flow losses in the 90-deg inlet turn are charged to the compressor efficiency. The entire performance of this compressor with regard to efficiency, pressure ratio, and stability is significant in that it was possible to calculate the performance of this unit and achieve the results shown in the curve, Fig. 8, without any modifications after tests.

FIG. 8 COMPRESSOR PERFORMANCE CURVE IMPELLER B

CONCLUSIONS

The analysis permits calculation of the impeller velocity distribution and gives a complete map of the velocity values for the three-dimensional compressible flow through the impeller of a compressor.

The use of the velocity-distribution curves permits the prediction of pulsation of the compressor. Pulsation occurs when the local velocity reaches values of zero or below.

A qualitative analysis can be made with regard to blade stalling by comparing velocity-distribution curves for similar types of impellers. The criterion for stalling may be defined as the deceleration per unit length $(\Delta w)/(\Delta l)$, or the pressure gradient per unit length $(\Delta p)/(\Delta l)$.

In making the qualitative analysis it must be pointed out that stalling is a function of boundary-layer thickness, and the boundary layer is affected by centrifugal force which acts to remove the boundary layer from certain locations of the blade. Hence it may be stated that radially ending vanes, or vanes which easily permit complete removal of the boundary layer due to centrifugal force, can have considerably larger values of the local pressure gradients before stalling occurs. On the other hand, impellers with backward leading blades, or vane shapes which do not permit removal of the boundary layer by centrifugal force but only a relocation of the boundary layer, are much more sub-

ject to stalling, and frequently, in units with small blade exit angle, stalling occurs before pulsation (11). The analysis of the velocity distribution also leads to the conclusion that impellers of maximum efficiency should, within certain limits, have fewer blades, thus increasing the Reynolds number but decreasing stability.

Finally, the flow in any machine is not frictionless but does follow the laws of an imperfect fluid. However, with the knowledge of the local velocity and pressure gradients, it should be possible to make better predictions about the behavior of the boundary layer and secondary flows. The knowledge of pressure gradients permits the application of the analysis of flow, including friction, as shown by J. R. Weske (12) and Goldstein (13), to these impellers.

The proposed method is applicable to mixed-flow compressors and to radial and mixed-flow turbines as well.

ACKNOWLEDGMENT

The author is deeply indebted to Prof. H. W. Emmons of Harvard University and the Elliott Company, Jeannette, Pa., for their permission to show the results of the relaxation method in Figs. 2 and 3, and to the Continental Aviation and Engineering Corporation, Detroit, Mich., for their permission to publish Figs. 5 to 8. The author is also indebted to Prof. J. R. Weske of Brown University, for the derivation of, and permission to publish, Equation [16].

Possibilities of the Regenerative Steam Cycle at Temperatures Up to 1600 F

By P. H. KNOWLTON¹ AND R. W. HARTWELL²

The regenerative-steam-cycle heat-rate gains that may be realized at temperatures up to 1600 F are presented in this paper. These gains are calculated for a theoretical cycle and also for a practical cycle wherein such losses as extraction-piping pressure drop, heater-terminal temperature differences, and the like, are considered. An economic evaluation of the anticipated turbine heat-rate differences for various throttle conditions is presented. This evaluation includes such factors as fuel costs, load characteristics, auxiliary-power requirements, boiler efficiencies, and annual fixed charges. A method of comparing the heat-rate gains due to higher steam temperatures with those made possible by resuperheating is provided.

THE purpose of this paper is to present the results of a study of the theoretical and practical possibilities of the regenerative steam cycle at throttle temperatures up to 1600 F. It also presents an economic evaluation of these gains which indicates the amount of capital investment which could be justified for the installation of high-temperature power-generating equipment.³

As the cost of fuel increases, it becomes more important to evaluate the savings which might be effected by increasing the steam temperatures in the power plant of the future. Because of the wide general interest in this problem, the ASME Special Research Committee on High Temperature Steam Generation requested the authors to prepare a paper covering (1) the probable thermal gains by the use of high-temperature steam in the regenerative cycle, and (2) the possible fuel savings that might result.

The use of steam for electric power generation has been characterized by a fairly steady increase in the steam temperature. This has made possible steady gains in the thermal efficiency of steam power plants. The increase in maximum steam temperatures used in power plants constructed during the past 45 years is shown in Fig. 1. This curve shows that the temperature has increased an average of 12 F per year. Perhaps more important is that the temperatures increased in steps as new high-temperature materials became available. During the past 20 years, temperatures have increased faster than the average rate of 12 F per year.

FIG. 1 MAXIMUM THROTTLE STEAM TEMPERATURES FOR PAST 45-YEAR PERIOD

THEORETICAL POSSIBILITIES AT HIGHER TEMPERATURES

Selvey and Knowlton⁴ published theoretical regenerative-steam-cycle heat rates for temperatures up to 1200 F and pressures up to 3200 psia. To facilitate a comparison over a wide range of pressure-temperature conditions, these data have been extended herein to 1600 F over the higher range of pressures, using the same theoretical cycle. As stated in the Selvey and Knowlton paper, the heat rates are for a regenerative steam cycle of the following component parts:

- 1 A turbine, having no mechanical losses, through which steam is expanded at constant entropy (engine efficiency is 100 per cent).
- 2 A regenerative feedwater system having an infinite number of bled-steam heaters heating to the saturation temperature, corresponding to the throttle steam pressure, and with zero terminal difference between the saturation temperature of the bled steam and the temperature of the feedwater leaving the heater, even when superheat is present in bled steam, and an attendant feed pump of 100 per cent efficiency with each heater to step up the feedwater pressure to the level of the next higher heater.
- 3 An electric generator of 100 per cent efficiency, which supplies, without line loss, the boiler feed pumps.
- 4 A steam generator of 100 per cent efficiency, in which blow-down, soot-blowing losses, etc., are zero.

Since energy required to drive fans, fuel equipment, general services, and so forth, is considered zero in a theoretical cycle, auxiliary-power usage other than that required for the boiler feed pumps, as described in item (2), is not included.

The theoretical heat rates are given in Table 1 and are presented in curve form in Fig. 2. This information shows that there is a steady improvement in the theoretical cycle economy with higher steam temperatures, but that the rate of improvement is diminishing as the temperatures are increased. Fig. 3 presents the theoretical heat-rate gains on a percentage basis with the 1250 psia-950 F throttle condition as a base. These curves provide a means of comparing theoretical and practical heat rates. The latter are discussed in the following section.

⁴ "Theoretical Regenerative-Steam-Cycle Heat Rates," by A. M. Selvey and P. H. Knowlton, Trans. ASME, vol. 66, 1944, pp. 489-500; discussion, pp. 501-512.

FIG. 2 THEORETICAL REGENERATIVE STEAM-CYCLE HEAT RATES

FIG. 3 PER CENT CHANGE IN THEORETICAL CYCLE HEAT RATE VERSUS INITIAL TEMPERATURE (Base condition, 1250 psia, 950 F, 1 in. Hg abs exhaust pressure.)

PRACTICAL POSSIBILITIES AT HIGHER TEMPERATURES

Fig. 4 shows comparative per cent change in regenerative-cycle heat rates which are considered practical from the design and operating standpoint. These heat-rate changes, computed for the same high-temperature and pressure range as was selected for the theoretical heat-rate calculations, include the effects of such losses as extraction-piping pressure drop, heater-terminal temperature differences, etc. From a specified heat rate for a particular turbine generator, the heat rate for any other condition may be calculated with the data included in Fig. 4.

As in Fig. 3, the base steam conditions chosen are 1250 psia, 950 F. The per cent change in heat rate from this base condition to any other condition may therefore be read directly. If it is desired to obtain correctly the difference in heat rate between any other two sets of steam conditions in terms of the heat rate at one of these conditions, the difference, as read from Fig. 4, must

be corrected for the change in base. For example, if we wish to get the difference between heat rates at 1450 psia, 1250 F and at 1450 psia, 1000 F, in terms of the heat rate at 1450 psia, 1000 F, this difference is

$$\frac{7.9 - 2.4}{1 - \frac{(2.4)}{(100)}} = \frac{5.5}{0.976} = 5.6 \text{ per cent}$$

Practical Cycle Assumptions. In making the calculations to

FIG. 5 PRACTICAL CYCLE HEATER ARRANGEMENT FOR HEAT-RATE CALCULATIONS

arrive at the values plotted in Fig. 4, the following assumptions have been made:

1 The cycle arrangement and associated apparatus have been assumed to be as shown in Fig. 5 which presents the same arrange-

ment as was used by Harris and White.⁵ The present calculations have been extended to higher temperatures and pressures than those assumed by Harris and White and are based upon somewhat lower boiler feedwater temperatures. Power required to drive the boiler feed pump has been deducted from the generator terminal output.

2 As was done in the Harris and White paper, turbine and generator efficiencies have been assumed to correspond to those obtained in present-day turbine generators. The turbine-generator efficiency assumptions correspond to those made by Warren and Knowlton.⁶ This implies that at temperatures above present-day levels, new features of turbine design, or new materials, or both, must be developed if the general level of efficiency obtained in the past is to be maintained.

3 The exhaust loss from the turbine has been assumed to be a constant fraction of the turbine power output for all steam conditions.

4 It is assumed that the turbine-generator output is about 100,000 kw. This must be borne in mind particularly when comparing the heat rates at various initial pressures, since turbines of smaller capacities than 100,000 kw probably would show poorer relative performance at the higher pressures.

Steam Flows. Throttle and condenser steam rates, based on the practical cycle assumptions, have been computed to indicate the relative size of the generating equipment. The throttle and

FIG. 6 THROTTLE STEAM RATE VERSUS INITIAL TEMPERATURE (1 in. Hg abs exhaust pressure.)

condenser steam rates are presented in Figs. 6 and 7, respectively. These are shown on the basis of the generator-terminal output, whereas the heat-rate change curves, Fig. 4, show the net change after deduction of boiler-feed-pump power from the generator-terminal output.

HEAT-RATE-DIFFERENCE EVALUATION

In considering the merits of one steam condition over another,

⁵ "Developments in Resuperheating in Steam Power Plants," by E. E. Harris and A. O. White, Trans. ASME, vol. 71, 1949, pp. 685.

⁶ "Relative Engine Efficiency Realizable From Large Modern Steam-Turbine Generator Units," by G. B. Warren and P. H. Knowlton, Trans. ASME, vol. 63, 1941, pp. 125-135.

it is desirable to evaluate the anticipated difference in heat rates. Because the practical heat rates represent results which at present appear possible at the higher steam conditions, these anticipated heat rates were used in this evaluation rather than the theoretical heat rates.

Basic Factors. The basic factors included in this evaluation are the cost of fuel, load characteristics, auxiliary-power requirements, boiler efficiency, turbine heat rates, and annual fixed charges on plant investment. Table 2 presents the results of an evaluation of heat-rate differences wherein a base condition of 1250 psia, 950 F has been used for comparing all of the other conditions. The figures shown in Table 2 represent the additional investment in dollars over the cost of 100,000 kw of 1250 psia 950 F capacity that is justified by the differences in heat rates. In computing the data it was assumed that plant availability and operating and maintenance personnel would be the same in all cases. No attempt was made to allow for possible differences in the extent of maintenance required.

Cost of Fuel. A 10-cent to 35-cent per million Btu fuel-cost range has been covered in the evaluation.

Load Characteristics. An annual plant-factor variation from 50 to 80 per cent has been included in the tabulation. The annual plant factor is the ratio of the kilowatthours generated on the machine in a year to the product of the kilowatt nameplate rating times 8760.

Auxiliary-Power Requirements. The following types of pulverized-coal-fired boilers were assumed in computing fan and mill power requirements:

FIG. 7 CONDENSER STEAM RATE VERSUS INITIAL TEMPERATURE

(a) For throttle pressures up to and including 2000 psia; natural-circulation boilers.

(b) For 2500 psia throttle pressure; steamotive-cycle boilers with recirculating pumps which handle 130 per cent of steam flow.

(c) For 3000 psia throttle pressure; once-through forced-circulation-cycle boilers.

Allowances for miscellaneous auxiliary-power demands were included in all cases.

Boiler Efficiency. A boiler manufacturer indicated that even with feedwater temperatures approaching 600 F on these high-pressure high-temperature boilers, the exit-gas temperature could be held to about 300 F. Assuming pulverized-coal boilers operating with an average grade of coal, it was estimated that boiler efficiencies would vary from 87.7 to 88.8 per cent, depending upon the feedwater temperature.

Turbine Heat Rates. Turbine heat-rate differences represented in Fig. 4, which are based on the practical values, were used in the evaluation.

Annual Fixed Charges. An annual fixed-charge rate of 10 per cent was assumed in computing the justified additional investments. The investment figures shown in Table 2 may be adjusted for other fixed-charge rates as follows:

$$\text{Investment from Table 2} \times \frac{0.10}{\text{New fixed charge rate}} = \text{adjusted investment}$$

Example. An example will illustrate the use of Table 2.

Throttle conditions to be compared: 1450 psia, 1000 F
3000 psia, 1400 F

Assumptions:

Coal cost..... 20 cents per million Btu
Annual plant factor..... 60 per cent
Fixed-charge rate..... 10 per cent

Additional investment figures from Table 2:

1450 psia, 1000 F..... \$ 259,000
3000 psia, 1400 F..... 1,503,000

The amount that could be spent for 100 mw of 3000 psia, 1400 F capacity over the cost of a 1450 psia, 1000 F installation is

$$\$1,503,000 - 259,000 = \$1,244,000$$

HIGH STEAM TEMPERATURES VERSUS RESUPERHEATING

It is of interest to compare the heat-rate gains resulting from higher steam temperatures with those made possible by resuperheating. An approximate comparison may be made directly by comparing gains shown in Fig. 4 with various charts by Harris and White, and by Reynolds.⁷ These two references do not exactly agree on the gain due to reheat, presumably because of differences in the assumptions made by the authors in setting up their calculations.

The assumptions made by Harris and White differ from those made in this paper on the following points:

1 The boiler feed temperatures are lower in the present case than were assumed by Harris and White. This difference makes a minor change in the gain due to reheat. For the order of magnitude of the effect of this on the reheat gain, refer to Reynolds' paper.⁸

2 The heat-rate gains in Fig. 4 of the present paper are on the basis of a fixed percentage exhaust loss, whereas Harris and White assumed, in calculating their reheat gain, that their non-reheat machines had a 4.5 per cent exhaust loss and their reheat machine a lesser exhaust loss obtainable from keeping the same exhaust-end size and the same rating for their reheat turbine. The assumptions made by Reynolds regarding the exhaust loss as between reheat and nonreheat are not stated in his paper.

However, we are able in the present case to show the effect of considering either two cases:

(a) The use of a "constant percentage exhaust loss," regardless of throttle-steam conditions. In this case, as we proceed to higher throttle temperatures, the exhaust size per unit rating decreases, and the gains expected are as shown in Fig. 4.

(b) The use of a "constant size of exhaust per unit rating," regardless of throttle-steam conditions. In this case, the percentage exhaust loss decreases when throttle temperature increases, and a further gain results from this, over and above the gains indicated in Fig. 4. The magnitude of this change in exhaust loss can be calculated by the use of Fig. 8, if the exhaust

FIG. 8 RELATIVE EXHAUST LOSS VERSUS INITIAL TEMPERATURE

loss at a base condition is known. For any two sets of steam conditions shown on Fig. 8, the ratio of exhaust-loss percentage is the ratio of the ordinates therein.

An example will illustrate this point:

Assume a base condition of 1450 psia, 1000 F, and compare heat-rate gains due to the following:

- 1 Reheat to 1000 F at 450-psia reheat pressure.
- 2 Raising throttle temperature to 1250 F, nonreheat.

The answer to (1) can be read from Harris and White⁹ as 5.2 per cent gain due to reheat, on the basis of constant exhaust size per unit rating.

The answer to (2) is given here in two parts, corresponding to the foregoing items (a) and (b), as follows:

(a) For constant percentage exhaust loss from Fig. 4, the gain at 1450 psia, 1000 F is 2.4 per cent, and at 1450 psia, 1250 F is 7.9 per cent. This gives a net gain of $\frac{7.9 - 2.4}{1 - 0.024} = 5.6$ per cent.

(b) For constant size of exhaust per unit rating, the relative exhaust-loss factors from Fig. 8 are as follows:

1450 psia, 1000 F..... 0.89

1450 psia, 1250 F..... 0.66

Revised exhaust-loss percentage from the assumed 4.5 per cent

$$4.5 \times \frac{0.66}{0.89} = 3.4 \text{ per cent}$$

Additional heat-rate gain due to exhaust-loss correction

$$4.5 - 3.4 = 1.1 \text{ per cent}$$

Total gain due to temperature increase

$$5.6 + 1.1 = 6.7 \text{ per cent}$$

It will be noted that the additional gain due to a change in the exhaust loss with fixed exhaust size depends directly upon the magnitude of the exhaust loss itself.

In comparing heat-rate gains due to higher steam temperatures with those made possible by resuperheating as presented by Harris and White, an exact evaluation should include the exhaust-loss correction described in item (b).

CONCLUSION

The curves for practical performance in Fig. 4 exhibit trends similar to those for the theoretical performance in Fig. 3. However it will be seen that the practical cycle shows less improve-

⁸ Footnote 5, Fig. 11.

⁷ "Reheating in Steam Turbines," by R. L. Reynolds, Trans. ASME, vol. 71, 1949, pp. 701-706.

⁸ Ibid., Fig. 5.

ment with increasing pressure, and more improvement with increasing temperature, than the theoretical cycle. This relationship results from the fact that the practical turbine loses in efficiency with increasing pressure, and gains in efficiency with increasing temperature, while the theoretical turbine is assumed to be always 100 per cent efficient. These trends are not at all new; the only novel feature is the extrapolation of the trends to show what economies may be expected at temperatures up to 1600 F and pressures up to 3000 psia. It is believed that this has been done in a reasonable manner consistent with past practice.

Use of steam temperatures in power plants above the present maximum of 1050 F will depend on the development of suitable materials for the higher temperatures and on the design of acceptable equipment, particularly boilers and turbines, at a cost commensurate with the thermal gains to be realized. Since the costs of such materials and equipment are not presently available, this paper has presented only the total investment which could be justified on the basis of the thermal gains expected at the higher steam conditions.

ACKNOWLEDGMENT

The authors wish to express their appreciation for the advice and assistance of Mrs. Jean Harrison Higley and Mr. E. E. Harris of the General Electric Company, Mr. A. E. Raynor of the Babcock & Wilcox Company, and Messrs. H. A. Wagner and H. S. Walker of The Detroit Edison Company.

Discussion

W. E. CALDWELL.¹⁰ This paper indicates the thermal performance and evaluated savings obtainable by increasing initial steam temperature for the regenerative steam cycle. This cycle offers advantages over the reheat cycle, from the standpoint of simplicity, although it would result in more water in the exhaust stages for the same heat rate. It is indicated that an initial temperature of about 1170 F with the regenerative cycle would yield about the same heat rate as a 1000-1000 reheat cycle with the same initial pressure and heater arrangement. In the arrangement of heating stages and distribution of extraction heaters, the regenerative cycle offers more attractive thermal possibilities than the reheat cycle. The question of economic justification for the regenerative cycle above present temperature limits must await practical developments in high-temperature metallurgy.

In both the reheat and high-temperature regenerative cycles the improved performance results from utilization of a larger proportion of high-level heat than is presently employed, which aggravates surface-cleaning problems in the boiler plant, aside from metallurgical considerations.

In a 1000-1000 reheat cycle, the heat required to superheat the steam and reheat it is equivalent to a drop of about 1350 deg F in boiler gas temperature. To this must be added 600 deg F saturation temperature, 200 deg F for temperature difference or heat head between gas and steam, and 150 deg F for gas stratification, resulting in temperature zones above 2200 F in the superheater bank. With the equivalent regenerative cycle a lower gas temperature suffices, but in both cases the required gas temperature is substantially above 2000 F, which is the approximate rejection limit for some abundant low-cost coals with low-fusion ash. Improvements in design and disposition of the superheater surface should, in time, lessen the cleaning requirements and extend the range of acceptable fuels for high-temperature installations. Geographical location of plants and characteristics of available fuels will continue to be a major consideration in the choice of steam conditions.

¹⁰ Staff Engineer, Consolidated Edison Company of New York, Inc., New York, N. Y. Mem. ASME.

This paper exemplifies our dependence upon the steam tables, and some comments on their use for the higher temperatures would be of interest. The upper temperature line on Mollier charts with the 1936 tables ends at 1200 F. Was a condition curve plotted for the expansions from the various initial temperatures, or was some other procedure employed?

E. E. HARRIS.¹¹ This paper will be a very useful tool for the industry. The user will be able to compare the gains to be expected as well as the amount of additional money that may be justified for obtaining a gain in station economy.

This paper, together with the paper by E. E. Harris and A. O. White,⁶ will give the user considerable information that may be used for determining the future trend in the power-plant field.

Fig. 4 of the paper was obtained from calculations that were made for the Harris and White paper with additional calculations made for the higher pressures and temperatures. The added calculations followed the same method as was used in the original paper, correcting for volume flow, pressure, and superheat, the superheat correction taking into account the change in moisture. It was assumed, in making the calculations and arriving at the gains to be obtained with higher pressures and temperatures, that materials will be available as well as design and ability to build such turbine units without sacrificing efficiency or gain.

At 1450 psia, 1000 F initial conditions, reheating to 1000 F will show a gain of approximately 5 per cent in station heat rate. If the same gain is to be obtained by operating at a higher initial temperature without reheat, the initial temperature will be about 1175 F. The 5 per cent gain in heat rate will justify an expenditure of \$632,000 over 1450 psia, 1000 F nonreheat with a coal cost of 30 cents per million Btu and 60 per cent annual plant factor. It is felt that a reheat station will have a lower increment cost than the nonreheat plant with 1175 deg to obtain the same gain.

Sometime in the future, materials will be available as well as design and know-how for building units for the higher temperatures for nonreheat. When such information is available, reheating to the same initial temperature may be used with approximately the 5 per cent gain over the nonreheat plant.

A. E. RAYNOR.¹² The authors have made an interesting and useful survey which should be helpful to those who are looking forward to the time when they may find it desirable to go to higher pressures and higher temperatures. Dollar values have been established and given in Table 2, which indicate approximately how much may be spent economically for the higher pressures and higher temperatures.

The data are presented with the bases used in establishing the dollar values, so that corrections may be made readily by anyone wishing to modify these data and correct for conditions which may differ somewhat from those arbitrarily used by the authors. Any correction which the user may wish to make, such as a different value for fixed charges, annual plant factor, etc., can be made readily, the additional justified investment quickly determined, and proper design conditions established.

The authors have been wise in extending the pressures to 3000 psia and the temperatures to 1600 F, even though manufacturers are not now equipped with materials to satisfy, particularly, the higher temperatures. It may be that we are now in a similar situation to the designers of, say, 20 years ago, when a temperature of 1050 F appeared to be very far in the future. However, in about 20 years, temperatures have gone from something less than 800 F to 1050 F, and higher temperatures will be used when satisfactory materials are available. Inasmuch as the wall

¹¹ General Electric Company, Schenectady, N. Y.

¹² Executive Assistant, New York Proposition Division, The Babcock & Wilcox Company, New York, N. Y. Mem. ASME.

thickness of some of the present $2\frac{1}{2}$ -in. 18 Cr, 8 Ni-Cb tubes used in the hot end of superheaters designed for 2300 psia and 1050 F are 0.56 in. thick, leaving but little internal area for the flow of steam, it is quite obvious that temperatures much higher than 1050 F will call for metals with higher available stresses than those currently being used. Many engineers in the steel and allied industries are working on this problem, and time alone will tell when the better high-temperature materials will be available for use. When one considers the economies gained by the use of higher temperatures, it may be that some will find it desirable to use higher temperatures even at the risk of shorter life of the material in the hot portions of the superheater, piping, and turbines. Therefore earlier replacement of parts of the equipment than now contemplated may be economically justified.

The authors indicate that, based upon certain assumptions, \$1,244,000 more may be spent for a 100,000-kw plant designed for 3000 psia, 1400 F than for a 1450 psia-1000 F installation. Using the same assumptions, \$773,000 more may be spent for a 2500 psia-1200 F installation than a 1450 psia-1000 F unit. In either case a considerable amount of money is involved. This alternative example is used because metals are already available and being used in reheat designs for 2080 psi 1050 F and 1000 F reheat, also 1500 psia 1000 F-1000 F reheat. The latter is about equivalent in cycle efficiency to the nonreheat 2500 psia-1200 F unit.

This presumably accounts for several companies purchasing reheat units during the past few years, the steam conditions being about as follows:

1300 psia, 950 F and 950 F reheat
1500 psia, 1000 F and 1000 F reheat
2080 psia, 1050 F and 1000 F reheat

Design engineers have had and will continue to have problems where a considerable amount of judgment is required in determining the best pressure and temperature to satisfy the conditions of a given project. The data submitted in this paper should be helpful in future studies and encourage engineers and metallurgists to solve the material problem as rapidly as possible in order that higher temperature metals may be available for early use.

R. L. REYNOLDS.¹³ In this paper the authors present the thermal advantages of high pressures and temperatures and point out the additional investment which can be justified by these reductions in fuel costs. Such a comparison with what are now considered established steam conditions (1250 psia, 950 F) will serve as a valuable guide for analyzing the benefits to be derived from these increased steam pressures and temperatures. It also offers a challenge to designers of steam generators and turbines to develop equipment to meet these advanced conditions.

Of particular interest are the curves in Fig. 4, which show the change in heat rates for pressures from 860 to 3000 psia and temperatures from 900 to 1600 F. We feel that the values given on these curves are consistent with past practice and are reasonable estimates of what can be expected in the future, provided developments in design and materials keep pace with increases in steam pressures and temperatures.

At the present time the maximum operating steam temperature on central-station turbines is 1050 F. Although operation at this temperature, in general, has been satisfactory, further successful operation should be experienced before extending this limit materially. In the meantime a thermal gain equivalent to about 175 deg F increase in throttle temperature can be realized by the use of the reheat cycle.

¹³ Land Turbine Engineering, Central Station Turbine Section, Westinghouse Electric Corporation, South Philadelphia, Pa. Mem. ASME.

The authors refer to the writer's paper,⁸ and point out that values for thermal improvement derived from the reheat cycle do not agree with those given by Harris and White,⁹ due to differences in the assumptions made.

These differences in assumptions are as follows:

(a) The writer's comparisons were made upon the turbine alone. It was pointed out that additional advantages were obtained due to a reduction of from 15 to 18 per cent in boiler-feed-pump power, but this factor was not included. Power requirements for condenser and boiler auxiliaries are also reduced by the use of the reheat cycle.

(b) The writer's data were based upon 1.5 in. Hg abs exhaust pressure, as compared with 1.0 in. Hg used by Harris and White. The increased exhaust pressure results in a smaller differential in the thermal advantages of the reheat cycle.

(c) The writer's values also were based upon a constant exhaust loss expressed in Btu per pound. It was pointed out that, if constant exhaust area for a given set of initial steam conditions were used, the 7 or 8 per cent decrease in exhaust volume would result in a decrease in exhaust loss and thus increase the thermal benefits from the reheat cycle.

When reduced to the same basis, the values given by Harris and White agree quite closely with the writer's.

The evaluation figures tabulated in the authors' paper have been based upon the assumption that equal reliability can be obtained for all sets of conditions. This may at first appear unjustified and certainly would be if the increased temperatures were attempted at this time, but, when operating experiences over a long period of time are studied, it is evident that the reliability of steam turbines is now higher than ever, despite a large increase in steam pressures and temperatures. Although each new step may result temporarily in some reduction in reliability until the problems associated with this advance are solved, we feel that, if these changes are made gradually and in a fundamentally sound manner, no decrease in reliability will be suffered.

L. B. SCHUELER.¹⁴ The authors have performed an excellent service in projecting the useful data on steam-electric unit heat rates into the field of higher steam temperatures, even into the extremes where most of us will probably never see their practical realization. However they give us an important sense of direction and show that there are real possibilities if we do not accept half-way measures in many respects.

The problem of whether to adopt higher steam temperatures rapidly resolves itself into some simple but definite economic limitations. The extremely high cost of alloy materials suitable for higher temperatures is the heart of the problem. The turbine builders already have taken the big step in going to austenitic materials for the high-temperature portion of the 1050 F units. It should be possible to extend the application of these materials up to about 1200 F for turbine construction.

The superheater design, wherein maximum metal temperatures are usually about 100 deg F higher than the steam temperature, indicates a limit of about 1000 F for the lower-cost ferritic-alloy materials. Higher temperatures involve correspondingly greater quantities of costly austenitic-alloy tubing—all based upon present allowable stresses as established by the ASME Boiler Construction Code. These present allowable stresses, while presumably based on reasonably long life along with a substantial safety factor, often represent conditions of indefinite life, say, more than 40 years. In these cases, and there are many of them, an extremely high initial investment is made in materials which might be difficult to justify in the light of experience.

¹⁴ Engineer, Mechanical Engineering Division, American Gas & Electric Service Corporation, New York, N. Y. Mem. ASME.

It is proposed that designers and users give consideration to the relative merits of designing superheater and reheater materials, particularly in the extreme high-temperature zones, with the deliberate intent that they shall have a limiting life, probably somewhere between 5 and 20 years. Careful studies of this proposal appear warranted, particularly in the light of substantial experience along these very lines in oil-cracking-still units. If studies indicate possible economic merit, then it becomes necessary to establish another set of higher allowable stresses, to be used in such applications, by the appropriate regulatory bodies.

On the basis of a double-stress standard, a preselected portion of a superheater or reheater could be built to long or short-life standards, as desired, with the manufacturer and purchaser working out the best over-all arrangement, and with the user being reconciled to periodic replacement of a small portion of the superheater or reheater. If it were limited to superheater and reheater tubing materials only, and up to a limiting tube diameter, the safety element would be kept adequately under control.

The ASME Special Research Committee on High Temperature Steam Generation is embarking on a broad program of research to investigate materials which are suitable for steam temperatures up to 1500 F.

It seems advisable that an analytical study of the proposed double-stress standard be made at once so that the research work can be planned more effectively. This study can and should be made jointly by manufacturers and users to arrive at the proper relationship of physical and economic limitations.

AUTHORS' CLOSURE

The authors agree with Mr. Caldwell and Mr. Harris in their finding that the data presented show that an increase by about 175 F in initial temperature gives a gain in heat rate equivalent to that obtainable from reheat, and that at present this gain is

more economically obtained from reheat than from such a considerable increase in temperature.

The authors are grateful to Mr. Caldwell for inquiring as to how the turbine calculations were made. This point probably should have been more fully covered in the paper. The Keenan and Keyes Steam Table extends to 1600 F (the chart is plotted only to 1200 F) although very much skeletonized above 1200 F. It was necessary to extend the chart to 1600 F and fill in intermediate values between those given in the table by calculation. This was done by graphical means, using a large-scale plot of the constant-pressure specific heat to smoothly interpolate between table values. No extrapolation was necessary. The chart thus extended was used for plotting the turbine expansion lines, in accordance with the assumptions as stated in the paper.

Mr. Raynor's remarks concerning tube thicknesses presently required illustrate very well the necessity for stronger materials for very elevated temperatures. His suggestion that perhaps some parts should be considered as requiring more frequent replacement is interesting, but it is not clear that such considerations would result in any economic improvement.

The authors are also grateful for Mr. Reynolds' statements, both as to general corroboration of the findings of the present paper, and as to clarification of his own previous paper, reference 7. Further, the authors are in agreement with Mr. Reynolds' remarks concerning relative reliability.

Mr. Schueler's statements are quite to the point. The high cost of satisfactory materials, according to present knowledge, is the main reason why higher temperatures are not presently used. It seems to be too early to judge effectively whether stresses currently allowed are overconservative. However, the company with which Mr. Schueler is associated has for many years been building power plants using high temperatures and pressures, so their experience is very valuable.

Oil Holes and Grooves in Plain Journal Bearings

By S. A. MCKEE¹ AND H. S. WHITE,¹ WASHINGTON, D. C.

Data are presented showing the performance of plain journal bearings having various arrangements of oil holes and grooves operating in a four-bearing friction machine with forced-feed lubrication. Tests cover operation where the oil is fed through the bearing shell by means of five arrangements, including one, two, or four oil holes; one axial or one circumferential groove. Tests were also run with three arrangements for feeding oil from the center of a hollow shaft. These were one or two oil holes in the shaft, or one oil hole terminating in a flat on the surface of the shaft. Two clearance-diameter ratios were used with each arrangement. Test runs were made at constant speed and at a number of loads, which were unidirectional relative to the bearings. The data cover operation with one oil at one oil-inlet temperature and two speeds. In some of the tests the loads were increased until unstable lubrication was reached. The test results include the frictional characteristics, values of ZN/P at transition between stable and unstable lubrication, and data on thermal behavior and on oil flow. A summary of the general behavior of the various arrangements is given.

NOMENCLATURE

The following nomenclature is used in the paper:

- D = journal diameter, in.
- L = bearing length, in.
- C = running clearance (difference between bearing diameter and journal diameter), in.
- W = total load acting on bearing, lb.
- P = W/LD = pressure on projected area of bearing, psi
- N = speed of journal, rpm
- F = tangential frictional force, lb
- f = F/W = coefficient of friction
- Z = absolute viscosity of lubricant at atmospheric pressure and bearing temperature, centipoises (cp)
- H_t = rate of heat supplied to one bearing from both entering oil and bearing friction, in-lb per min
- ΔT_b = temperature rise above ambient of loaded side of bearing shell (average of four bearings), deg F
- ΔT_s = temperature rise above ambient of oil leaving ends of bearings (average of four bearings), deg F
- Q = rate of oil flow per bearing, cu in. per min
- ZN/P = generalized operating variable
- p = oil-feed pressure (corrected for drop between gage and bearings and for centrifugal force when oil is fed through shaft), psi

INTRODUCTION

One of the problems in the lubrication of plain journal bearings is the method of admitting the oil to the bearing. The concept of the load-carrying film indicates the desirability of avoiding the use of oil holes or grooves which interfere with the normal development of hydrostatic pressure to support the load. In some bearing installations, however, it is not always possible to satisfy this requirement. With bearings where loads are fluctuating in both intensity and direction, it is sometimes impracticable to apply the oil to the unloaded side throughout the complete load cycle. Also in some cases, provision must be made for a continuous flow of oil to some other moving part.

The tests reported in this paper were made to determine the comparative performance of journal bearings having various arrangements of holes or grooves when using forced-feed lubrication under conditions where in each case the load was unidirectional on the bearing. The work comprised two separate series of tests. The first covers operation with three arrangements of oil holes and two types of oil grooves in the surface of the bearing. The second covers operation with three arrangements for feeding the oil from the center of a hollow shaft. Each of these arrangements is located at the axial center of the bearing.

This investigation was part of a research program on the lubrication of plain journal bearings which was conducted at the National Bureau of Standards with the financial support of the National Advisory Committee for Aeronautics.

APPARATUS

Four-Bearing Friction Machine. The four-bearing friction machine used in this investigation has been described in a previous publication (1).² The complete apparatus is shown in Fig. 1, and the major elements of the machine disassembled in Fig. 2. The machine consists essentially of four similar test bearings enclosed in a housing and mounted on a common shaft. Loads are applied by hydraulic jacks which form the base of the housing. The complete unit of bearings and housing acts as a cradle dynamometer. The frictional torque is measured by a dynamometer scale acting through a torque arm fitted to the housing. An automatic device is provided in the hydraulic system to release the load under the high-torque conditions occurring near bearing seizure.

In the first series of tests, oil was fed to each bearing through conventional pipe and tubing, using flexible connections to the bearing housing. In the second series, the oil was fed to the end of the hollow shaft through a rotating joint. The lubricating system was provided with a vane pump having a variable-speed drive and a relief valve. Runs could be made at constant oil-feed pressure or at a constant rate of oil flow. The oil-feed line also was fitted with a filter consisting of two layers of sheet cellulose, electric heaters for controlling the oil-inlet temperature, and a flowmeter used chiefly for control purposes. Determinations of oil flow also were made by weighing the amount of oil that flowed for a given time interval from the housing outlet into a measuring vessel.

² Numbers in parentheses refer to the Bibliography at the end of the paper.

FIG. 1 FRICTION-MACHINE INSTALLATION

Operating temperatures were measured with copper-constantan thermocouples. One was fastened to the loaded side of each of the four bearings, and four thermocouples of equal resistance con-

nected in parallel, were spaced around the shaft, in the oil streams at the end of each bearing.

Shafts and Bearings. One solid test shaft was used in all of the first series of tests. It was made of SAE 3115 steel, carburized, and heat-treated to a hardness of 55 Rockwell C. The three hollow test shafts, $\frac{7}{16}$ in. inside bore, used in the second series of tests, were made of SAE 4615 steel, carburized, and heat-treated to hardnesses ranging from 58 to 61 Rockwell C. The surface roughness of each shaft was measured at 90-deg intervals at each of the four journal positions.

The averages of the observations for each shaft ranged from 4 to 5 microinches (rms profilometer). The journal diameters were measured 90 deg apart at each of the four journals on each shaft. The observations of diameters were accurate to 0.00005 in. at 68 F.

The shaft used in the first series of tests had no holes or grooves. In the second series, the shaft used with bearing sets S31, and S51 (see Fig. 3), had one radial oil hole at the mid-point of each bearing. The holes were 0.125 in. in diam and were chamfered to a diameter of approximately 0.180 in. at the shaft surface. The one used with bearing sets S32 and S52 was similar, except that two holes 180 deg apart were used for each bearing. The shaft for bearing sets S33 and S53 was similar to the shaft with one hole per bearing, except that instead of a chamfer, a flat, $\frac{5}{16}$ in. long (axially) and $\frac{3}{16}$ in. wide (depth about 0.004 in.), was located symmetrically at the end of each hole. The edges of the chamfers and flats were stoned and polished to remove sharp edges.

The test bearings were solid steel sleeves with copper-lead linings conforming to Pratt and Whitney Aircraft specification 121. They were pressed in the bearing retainers, rough-bored in a lathe, pushed in the self-aligning ball-bearing swivels, and then

FIG. 3 ARRANGEMENTS OF OIL HOLES AND GROOVES IN BEARINGS

finished to size with a special type of bearing reamer having a single cutting edge. With each bearing, determinations of four diameters 45 deg apart were made at each of three axial positions, one at the center, and one near each end. Bearings having circumferential grooves were measured on each side of the groove as well as at the ends. These measurements were accurate to 0.0001 in. at 68 F.

Bearings with one, two, or four oil holes, or with one circumferential or one axial groove were used in the first series of tests. Sketches showing the details of these arrangements are given in Fig. 3. With any of these arrangements each hole or groove was connected with the source of oil supply. In the second series of tests, the bearings had plain cylindrical surfaces. Two sets of bearings of different clearance were run for each type of oil feed.

The essential dimensions of the shafts and bearings are given in Table 1.

LUBRICANT

The oil used in these tests was an SAE 20 motor oil having an absolute viscosity of 70.8 centipoises at 100 F and 8.12 centipoises at 210 F.

FRICTION DATA

Tests at High ZN/P . With each set of bearings, tests first were made in the region of stable lubrication at the higher values of ZN/P (see nomenclature) in order to obtain characteristic data with a minimum of change in bearing surface. Each test run was made at a constant speed with a number of constant loads which were successively increased at intervals during each run. The apparatus was "warmed up" before the start of each test run and the data were obtained with the bearings in a steady state of temperature distribution.

Friction data obtained in these tests are given in Figs. 4, 5, 6, 7, 8, 9, 10 and 11 for the eight oil-feed systems. These results cover operation at an oil-inlet temperature of 200 F, two speeds, 2030 and 3040 rpm, and a range of loads from approximately 300 to 3000 psi on the projected area. In these figures f , the coefficient of friction, is plotted against the operating variable ZN/P . The values of Z used are based on temperature observations obtained with the thermocouples on the loaded side of each bearing shell.

With the bearings having a circumferential groove, the effective area of the loaded side of the bearing is reduced, and in plotting the data shown in Fig. 8, the values of P used were based on the effective area (total area minus area of groove). The slopes of the curves would be somewhat less if P were based on the total projected area of the bearing as was the case with the curves for the other designs of bearings.

Lines representing the Petroff equation for concentric running (2) for the respective D/C ratios used are also shown in the figures. The experimental data for a given bearing can be represented by a straight line roughly of the same general slope but displaced toward greater values of f than is given by the Petroff line for a given D/C ratio. This general trend of the data is similar to that obtained in an earlier investigation (3) where it was shown that the friction of a journal bearing could be represented approximately by the equation $f = k(ZN/P)(D/C) + \Delta f$, where Δf was an L/D correction and represents the difference (approximately) between the experimental data and the Petroff equation.

For purposes of comparison, values of Δf at $ZN/P = 10$ and $ZN/P = 70$ for each set of bearings tested are given in Table 2. The table also lists the average value of Δf (over the range of ZN/P from 10 to 70) for each set, and the average value for each type of bearing (two D/C ratios). The latter values are used as

a basis for rating the different types of bearings from the standpoint of friction. Since the differences between some types are within the probable experimental error, the ratings are given in three general groups: Group A, bearings of relatively low friction; B, intermediate; and C, high.

One of the most marked effects shown by the data given in this table is the relatively high friction obtained with the bearings having a circumferential groove, where the bearing is divided into two narrow bearing surfaces. This confirms the results obtained by Clayton (4). It also is in agreement with previously published data obtained at the National Bureau of Standards (3), which indicate that for L/D ratios less than unity, a decrease in L/D increases the friction. The data for this type of bearing were based on the effective area rather than the total area. If the latter is considered, the average value of Δf for this type of bearing would become 0.00217 instead of 0.00240 as given in Table 2.

The data for the bearings having two oil holes and four oil holes, of which one and two holes, respectively, were on the loaded side of the bearing, showed a slightly higher friction than for the sets having one hole or one axial groove, where the loaded side was undisturbed.

It is of interest that with the sets where the oil was fed through the shaft, there was only a relatively small increase in friction, although, during part of a revolution of the shaft, an oil hole was passing through the loaded portion of the bearing. This small increase is especially interesting with sets S33 and S53 where there was a relatively large flat on the shaft.

Tests at Low ZN/P . After the tests at high ZN/P , the range of operation with each set of bearings was extended to cover the lower values of ZN/P at and below the point of minimum f . In each test the speed and rate of oil flow were held constant and the load was increased in steps until unstable lubrication was reached.

TABLE 2 FRICTION RATINGS OF BEARINGS

Design of oil feed	Bearing set	$ZN/P=10$ Δf	$ZN/P=70$ Δf	Average Δf for each set	Average Δf for each design	Friction rating
1 hole in bearing	S1	0.00101	0.00149	0.00125	0.00130	A

One of the chief difficulties in obtaining representative data in the unstable region of lubrication is that the frictional characteristics of the bearings are affected by the roughness, geometry, and metallurgical features of the bearing surfaces, and, under operation, these frequently do not remain constant very long. Usually a bearing first tends to improve from the so-called running-in action (5), but when operation is continued under relatively high loads, speeds, and temperatures, the performance frequently is impaired and sometimes to a considerable degree. Accordingly, in running these tests, precautions were taken to minimize such effects by holding the bearings at a given load and speed for a relatively short time (2 min).

Friction data obtained in the first and fourth test runs when operating at 2030 rpm and with 15 cu in. per min oil flow with each of the eight designs of bearings are given in Figs. 12, 13, 14, 15, 16, 17, 18, and 19, where f is plotted against ZN/P . In Fig. 16 (as was the case in Fig. 8), the values of ZN/P used in plotting the data are based upon the effective area of the bearings.

In Figs. 12 to 19, inclusive, the differences between the curves for the first and fourth runs provide an indication of the change in bearing performance with running-in for a given set of bearings.

In these tests the bearings were operated at a given load for a period of 2 min (as was previously mentioned), and observations of the frictional torque were made at 1-min intervals. The values

of f given in the figures are based upon the second observation where conditions were more nearly in a steady state. One ex-

FIG. 17 FRICTION IN UNSTABLE REGION FOR 2-IN. \times 1 $\frac{1}{4}$ -IN. COPPER-LEAD BEARINGS WITH ONE OIL HOLE IN SHAFT (Operating at 2030 rpm, 15 cu in. per min oil flow, SAE 20 oil at 200 F oil-inlet temperature.)

FIG. 18 FRICTION IN UNSTABLE REGION FOR 2-IN. \times 1 $\frac{1}{4}$ -IN. COPPER-LEAD BEARINGS WITH TWO OIL HOLES IN SHAFT (Operating at 2030 rpm, 15 cu in. per min oil flow, SAE 20 oil at 200 F oil-inlet temperature.)

ception to this is at the highest load in a given run where the friction rose rapidly and the automatic load release usually acted within 30 sec. When operation was in the region of stable lubrication, the second torque reading was either equal to or lower than the first, depending upon the particular rates of heating and cooling and the time required to reach a steady state.

As the loads were increased, the bearings eventually reached the unstable operating condition where the friction increased with an increase in temperature. In some of these tests this transition from stable to unstable conditions is fairly well defined by the friction curves, because the frictional torque rose rapidly and usually in a very short time reached a value high enough to trip the load release. In others, however, the change in the friction curve was more gradual, and the transition is more definitely indicated by the condition where the second torque reading is higher than the first. In Figs. 12 through 19, the approximate locations of these points of transition between stable and unstable lubrication obtained during the first test run with the bearings having a D/C ratio of 663 are indicated by the letter a and for the fourth run by A . Corresponding points obtained with the bearings having a D/C ratio of 403 are indicated by the letters b and B .

The critical values of ZN/P at which these transition points occur for the first and fourth runs with each set of bearings are given in Table 3. Also listed are the average values obtained with each type. Since the first run with each set of bearings may be significantly affected by the condition of the original surface finish, the values for the fourth run are used as a basis for rating the different types. These ratings provide an indication of the relative load-carrying capacity of the bearings when operating under the given conditions. They are indicated by letters rather than the numerical values, since (as was the case with the friction data at high ZN/P) the differences between some types are within the probable experimental error.

From the data given in Table 3 it will be noted that the values of ZN/P when unstable lubrication was reached were, in general, lower with the bearings having no holes or grooves on the loaded side (sets 31, 51, 33, and 53). In this connection, however, it is of interest that while the values obtained with the sets having one or two holes in the shaft were somewhat higher, they were sufficiently low to receive an A rating. Under the conditions of operation in these tests, the passage of an oil hole through the loaded portion of the bearing had relatively small effect on the points of transition between stable and unstable lubrication.

With the sets having a flat on the shaft, the reduction in area

FIG. 19 FRICTION IN UNSTABLE REGION FOR 2-IN. \times 1 $\frac{1}{4}$ -IN. COPPER-LEAD BEARINGS WITH ONE HOLE WITH FLAT IN SHAFT (Operating at 2030 rpm, 15 cu in. per min oil flow, SAE 20 oil at 200 F oil-inlet temperature.)

was sufficient to cause a marked increase in the value of the critical ZN/P , and these sets have the lowest load-carrying capacity rating.

Because of the interference to the formation of a load-carrying film with the bearings having two holes, four holes, or a circumferential groove, the operation was impaired sufficiently to result in intermediate ratings. If the total area is considered for the bearings with a circumferential groove, the average critical value of ZN/P would increase from 2.8 to 3.1 and would change the rating from B to C .

The small difference between the bearings with the axial groove and with one oil hole indicates that the groove may be somewhat more effective in the distribution of the oil for maintaining the load-carrying film.

THERMAL BEHAVIOR

Data pertaining to the thermal behavior of these bearings were obtained in the tests at high ZN/P values under a steady state of temperature distribution. In the analysis of these data, consideration is given to the total heat supplied to the bearing. Since the oil-inlet temperature was higher than the ambient temperature, the temperature rise of the bearings was not only dependent upon the heat generated by shearing the oil in the bearings but also upon the heat delivered by the oil entering the bearings.

TABLE 3 LOAD-CARRYING CAPACITY RATINGS OF BEARINGS

Design of oil feed	Bearing set	First Run		Fourth Run		Load-carrying capacity rating
		Critical ZN/P for each set	Average critical ZN/P for each design	Critical ZN/P for each set	Average critical ZN/P for each design	
1 hole in bearing	31	3.2	3.2	1.7	1.6	A
	51	3.1	3.2	1.5	1.6	
2 holes in bearing	32	3.6	3.6	2.6	2.7	B

	55	4.2	4.2	3.2	2.8	
1 hole in shaft	S31	2.2	2.6	1.9	1.8	A
	S51	3.0	2.6	1.8	1.8	
2 holes in shaft	S32	2.7	2.8	2.0	1.9	A
	S52	3.0	2.8	1.8	1.9	
1 hole with flat in shaft	S33	7.2	7.4	5.5	5.4	D
	S53	7.7	7.4	5.2	5.4	

The thermal data obtained with the two sets of bearings of different C/D ratios having a circumferential groove (sets 35 and 55) are given in Fig. 20. In this figure, H_t , the total rate of heat supply to one bearing from both the entering oil and bearing friction (expressed in in-lb per min) is plotted against the temperature rise above the ambient. The solid points indicate the rise in temperature above the ambient of the oil leaving the bearings (ΔT_o), as determined by thermocouples located in the oil streams at the ends of each bearing, while the open points represent the temperature rise of the bearings (ΔT_b) as determined by thermocouples placed in the loaded sides of the bearing shells. Since these tests were made at a steady state of temperature distribution, the data are also indicative of the rate of heat dissipation.

Analysis of the data in this figure indicates that the relation between the rate of total heat supplied to the bearings and the temperature rise above the ambient is dependent chiefly upon factors affecting the rate of heat dissipation by the oil, namely,

FIG. 20 THERMAL BEHAVIOR OF 2-IN. \times 1 1/4-IN. COPPER-LEAD BEARINGS HAVING A CIRCUMFERENTIAL GROOVE IN BEARING. Operating at 2030 and 3040 rpm. SAE 20 oil at 200 F oil-inlet temperature.)

rate of oil flow, specific heat of the oil, and temperature rise of the oil. This method of analysis has been outlined in detail in a previous publication (6), which also describes a method for determining from the data the rate of heat dissipation through the apparatus itself by radiation, conduction, and convection.

The lines drawn in Fig. 20 represent the H_t versus ΔT_o relationship for the indicated constant rates of oil flow (Q expressed as cu in. per min). The line $Q = 0$ represents the heat losses through the apparatus itself, and is used as a base for computing the lines representing the H_t versus ΔT_o for the different values of Q . These are obtained by computations involving the product of the rate of oil flow indicated, the temperature rise, and the average specific heat of the oil over the given temperature range. From the figure it will be noted that these computed lines are in reasonable agreement with all the experimental data based upon values of the average temperature above the ambient of the oil leaving the bearings.

In Figs. 21 and 22, H_t versus ΔT_o data are given for all sixteen sets of bearings when operating at 2030 rpm and a rate of oil flow of 15 cu in. per min. From these figures it will be noted that the data for all the bearings, having various arrangements of holes, or grooves, show the same general trend and fall reasonably well on the computed lines. This indicates that under the conditions covered, the heat-dissipation characteristics of the bearings were dependent chiefly upon the rate of oil flow through the bearings and were practically independent of clearance or the type of hole or groove used.

OIL FLOW

Measurements of the rate of oil flow at various oil-feed pressures were made also with each set of bearings when operating at a given load and speed. The flow-pressure data obtained with the bearings having a D/C ratio of 663, when operating at a load of 3008 lb per bearing ($P = 1148$ psi) and a speed of 2030 rpm, are given in Fig. 23, where Q , the rate of flow per bearing in cubic inches per minute is plotted against p the corrected oil-feed pres-

FIG. 21 THERMAL BEHAVIOR OF 2-IN. \times 1 $\frac{1}{8}$ -IN. COPPER-LEAD BEARINGS

(Operating at 2030 rpm, 15 cu in. per min oil flow, SAE 20 oil at 200 F oil-inlet temperature.)

FIG. 22 THERMAL BEHAVIOR OF 2-IN. \times 1 $\frac{1}{8}$ -IN. COPPER-LEAD BEARINGS

sure in pounds per square inch. Similar data for the bearings, having a D/C ratio of 403, are given in Fig. 24.

It should be pointed out that the data in these figures were obtained at constant load and speed but because of temperature changes caused by differences in friction and oil flow they were not obtained at constant viscosity.

The flow characteristics shown by these curves are dependent upon the particular operating conditions, hence the relative values are not necessarily applicable to other conditions. They are also dependent upon the particular dimensions of the holes and grooves used and changes in these dimensions may affect the relative values materially.

The most marked characteristics shown by these oil-flow data are the relatively high rates of flow obtained with the bearings

having the axial or circumferential oil grooves and the generally low rates obtained with the sets where the oil was fed through the shaft.

Since the rate of heat dissipation of the bearings depended chiefly upon the rate of oil flowing through the bearings, these flow data provide an indication of the relative heat-dissipation characteristics of the bearings tested under the operating conditions covered.

CONCLUSION

The influence of the various arrangements of oil holes and grooves on the behavior of bearings is as follows:

One Oil Hole in Bearing. With this arrangement, the absence of holes or grooves on the loaded side of the bearing provides for normal development of pressure in the oil film. Consequently, the bearing has relatively low friction and low ZN/P at transition between stable and unstable lubrication. While the single hole does not provide the highest oil flow, it would seem to be sufficient to provide adequate heat dissipation for most conditions.

Two-Oil-Hole Arrangement in Bearing. The single hole on the loaded side with this arrangement apparently disturbs the normal development of pressure in the film to make a measurable increase in friction and in ZN/P at the transition point. The par-

ticular location of the oil hole on the unloaded side is adverse from the standpoint of oil flow, hence the rate of heat dissipation is somewhat lower than the arrangement with one hole in the bearing.

Axial Groove in Bearing. This arrangement apparently provides a slightly better distribution of oil for the development of the load-carrying film than the arrangement with one hole in the bearing. Consequently, the bearing has low friction and lowest critical ZN/P , and the high oil flow provided is advantageous where forced cooling is necessary.

Four-Hole Arrangement in Bearing. This arrangement has two holes on the loaded side which disturbs the development of pressure in the film to a greater extent than the arrangement with two holes in the bearing, and its critical ZN/P is higher, but the friction is comparable. The two holes on the unloaded side are not in advantageous positions, and its oil flow and rate of heat dissipation is comparable to the arrangement with one hole in the bearing.

Circumferential Groove in Bearing. The groove dividing the bearing into two narrower parts increases the friction and causes a relatively high critical ZN/P . The high friction is counteracted by high oil flow and rate of heat dissipation.

One Oil Hole in Shaft. The passage of one oil hole across the loaded portion of the oil film has relatively small effect on both friction and critical ZN/P , which are only slightly higher than for the arrangement with one hole in the bearing. When the hole is exposed to some portions of the loaded area, the oil feed is practically shut off and consequently this arrangement results in the lowest oil flow and rate of heat dissipation.

Two Oil Holes in Shaft. With two oil holes for each journal, the disturbance to film-pressure development occurs twice in a revolution, resulting in slightly higher friction and critical ZN/P than with the arrangement with one hole in the shaft. The two holes also provide a greater oil flow and rate of heat dissipation. In this respect it is comparable to the arrangement with two holes in the bearing.

One Oil Hole With Flat in Shaft. The flat at the end of the oil-hole causes considerable disturbance to the development of pressure in the oil film, increases the friction, and markedly increases the critical value of ZN/P . Its oil flow and rate of heat dissipation are higher than the arrangement with one hole in the shaft without the flat but not sufficient to counteract the effect of its high ZN/P at transition from stable to unstable lubrication.

The results of these tests apply directly to unidirectionally loaded bearings for the particular range of conditions covered. The indicated differences between the various arrangements are not necessarily strictly indicative of more complex conditions where the load varies in both intensity and direction with respect to the bearings. It is believed, however, that the relative values obtained may be useful qualitatively in estimating the over-all effects of various arrangements of holes or grooves under more complex loading conditions, especially if proper consideration is given to conditions present throughout the complete load cycle.

Discussion

M. D. HERSEY.³ Can the authors compare their results at any point with the work of Clayton and others, and amplify their application to engine bearings?

AUTHORS' CLOSURE

With reference to Mr. Hersey's question, the case of the bearings with 360-degree circumferential groove provides the closest approach to a direct comparison between our results and those of Clayton (4). Clayton's bearing h and our bearing set 35 are similar in diameter and length but differ in D/C ratio, that value for bearing h being 800 and for set 35 being 663. In Table 1 in his paper Clayton reports a value of the coefficient of friction of 0.0026 for bearing h when operating at a speed of 3000 rpm, a load of 1500 psi, and with the viscosity of the oil at 10.0 centipoises. Under these conditions the value of ZN/P is 20. The value of f for $ZN/P = 20$ for set 35 is about 0.00275. This is shown in Fig. 8 of our paper. An approximate correction to this value (based on the Petroff equation) to correspond to a D/C ratio of 800 would raise the value to about 0.00288. This would indicate that the value we obtained was about 10 per cent higher than that obtained by Clayton. In this connection, however, it should be pointed out that the NPL friction machine used by Clayton measures the bearing friction, whereas the NBS four-bearing friction machine measures the journal friction (see Norton's "Lubrication," 1942, p. 23). This difference in f in the two cases would seem to indicate that along a line perpendicular to the load the center of the journal was displaced from the center of the bearing about 0.00028 in., and, if it is assumed that the film thickness at the point of closest approach is somewhat smaller than the 0.0002 in. estimated by Clayton for bearing a (bottom hole), the angle between the line of the load and the point of closest approach would be of the order of 14 degrees. Since both of these values appear to be reasonable, it is believed that the friction data for the two bearings check rather closely.

Somewhat greater differences in f are shown when comparing Clayton's bearing a (one oil hole in unloaded side) with our set 31. However, this can be accounted for by the difference in L/D , which was 0.875 for bearing a and 0.620 for set 31.

Comparison of the data on oil flow is more difficult because of the complex relations between the factors involved. Rough corrections for differences in clearance, length, viscosity, and oil-feed pressure indicate that values from the two laboratories for similar types of bearings are of the same order of magnitude, but no attempt was made to evaluate the effects of differences in such factors as oil-inlet temperature, load, speed, or eccentricity.

Film Thickness Between Gear Teeth

A Graphical Solution of Karlson's Problem

By M. D. HERSEY¹ AND D. B. LOWDENSLAGER²

This investigation completes a solution, undertaken by K. G. Karlson in his little-known Swedish paper of 1926, for the oil-film thickness between gear teeth. Karlson's problem is characterized by the use of a parabolic curve for the viscosity-pressure relation. The numerical results here obtained are comparable with those previously published by Gatcombe, who used a more conventional viscosity-pressure formula. It is hoped that the present analysis will help to clarify the assumptions and calculations required in the hydrodynamic theory of gear-tooth lubrication. As an aid to its practical application, the relative film thicknesses found for geometrically similar pairs of gears are here shown by a chart constructed in terms of the appropriate dimensionless variables, and extending from zero to 10 microinches per in. of pitch diameter of the pinion. The limiting case of a lubricant whose viscosity is unaffected by pressure, for which an analytical solution had been given by Karlson, is represented by a straight line on this chart.

INTRODUCTION

It would be useful in studies of gear-tooth lubrication, particularly when efforts are being made to increase the load capacity of gear teeth, to be able to estimate, even roughly, the probable or possible thickness of the oil film between two contacting teeth under hydrodynamic conditions.

Three principal investigations toward this end have already been published, those of *Engineering* in 1916 (1),³ of Karlson in 1926 (2), and of Gatcombe in 1945 (3). The article in *Engineering*, though unsigned, is generally recognized as the pioneer investigation in our field. It does not, however, take into account the effect of high pressure on viscosity. The study by Karlson is based upon a parabolic equation for the viscosity, Z , of the lubricant as a function of the gage pressure p , namely

$$Z = Z_1 \left(\frac{p + k}{k} \right)^2 \quad [1]$$

where Z_1 is the viscosity at atmospheric pressure and k is a constant of the lubricating oil. Gatcombe's study is based upon a widely used exponential formula

$$Z = Z_1 (10)^{p\delta} \quad [2]$$

where δ is an empirical constant analogous to k .

NOTE: Statements and opinions advanced in this paper are to be understood as individual expressions of their authors, and not those of the Navy Department, the Naval Service at large, or the Society. Manuscript received at ASME Headquarters, January 11, 1950. Paper No. 50-S-10.

Karlson's investigation was left unfinished, his integral for the load capacity of the film not being evaluated. Gatcombe's study was carried through and applied to a series of numerical examples. These numerical results were generalized by Hersey and Hopkins (4), in the form of a chart for the relative film thickness in geometrically similar gears. However, Blok (5) has questioned the accuracy of Gatcombe's mathematical approximations leading to the results utilized by Hersey and Hopkins. Accordingly, the present authors found it necessary to make a fresh approach to the subject, and therefore undertook a graphical solution of Karlson's problem.

BASIC ASSUMPTIONS

The physical assumptions which are customary in the theory of lubrication, and others pertinent to the gear-tooth problem, notably the following, have been made:

1 The lubricant is incompressible and without inertia; it has the same physical properties at every point and in every direction; it adheres to the solid surfaces and follows Newton's law of viscous flow.

2 The gear teeth are rigid and geometrically perfect, and therefore free from any appreciable effects of deformation, misalignment, manufacturing errors, surface roughness, or wear.

3 The gears are running at constant speeds without dynamic loading or appreciable vibration.

4 The temperature is uniform throughout the film at any moment, though it may vary greatly with operating conditions.

5 The mechanical action of the film has reached a practically steady state at every phase of contact, or angular position of the tooth; the approach process being so nearly completed that the minimum film thickness in every such position may be treated as a constant with respect to time.

These various assumptions define the scope of our investigation and limit it severely compared to what might ideally be desired (6, 7). It is hoped, however, that the present analysis may be useful in the absence of more exact knowledge, and that it may be followed by discussions which will greatly clarify the background of gear-tooth lubrication theory, thus facilitating the work that lies ahead.

INTEGRATION FOR LOAD CAPACITY

The normal tooth load F_n , which is the resultant force per unit of face width exerted by one tooth upon another at right angles to the tooth surface through the medium of the oil film, is given by

$$F_n = \int p \, dx \quad [3]$$

where p denotes the fluid pressure at any distance x measured in the direction of motion from the point of nearest approach.

Karlson's expression for the pressure distribution, derived from the usual hydrodynamic assumptions together with Equation [1] may be written

$$p = \frac{4HTk}{(1+T^2)^2 - 4HT} \quad [4]$$

Here T is the tangent of Gatcombe's angle S , and may be defined by

$$T \equiv \frac{-x}{\sqrt{2r h_0}} \quad [5]$$

where h_0 denotes the film thickness at the point of nearest approach; and r denotes the effective contact radius, defined by

$$\frac{1}{r} \equiv \frac{1}{r_1} + \frac{1}{r_2} \quad [6]$$

in which r_1 and r_2 are the radii of curvature of the pinion tooth and gear tooth, respectively. The dimensionless number H in Equation [4] is defined by

$$H \equiv \frac{Z_1 U \sqrt{2r h_0}}{k h_0^3} \quad [7]$$

where U denotes the mean tangential velocity $(U_1 + U_2)/2$ of the contacting surfaces, U_1 referring to the pinion and U_2 to the gear. It happens that H is equal to $1/12$ the ratio of Gatcombe's constant G to Karlson's constant k , both of which have the dimensions of pressure.

From Equation [4] it will be noted that $p = 0$ when $T = 0$, and, therefore, when $x = 0$. Thus the film pressure is assumed to vanish at the point of nearest approach. This assumption is known as Sommerfeld's condition, in contrast with Reynolds' condition under which both the film pressure and the pressure gradient vanish together at some point in the divergent portion of the film, appreciably removed from the point of nearest approach in the direction of motion. While the present authors subscribe to Reynolds' condition, they have tolerated the other for simplicity in completing Karlson's integration. A trial calculation indicates the difference in load capacity under the two assumptions to be of the order of 15 per cent, more or less, Reynolds' condition leading to the greater load capacity; hence our solution will be on the safe side. Both schools of thought concur for practical purposes in disregarding the region of negative pressure; hence the integration of Equation [3] need be carried out only on one side of the point of nearest approach.

Substituting from Equations [4] and [5] into [3] gives for the normal load per unit width

$$F_n = \frac{2 Z_1 U r}{h_0} \left(\frac{J}{H} \right) \quad [8]$$

where by definition

$$J \equiv \int_0^{\infty} \frac{4 H T dT}{(1 + T^2)^2 - 4 H T} \quad [9]$$

Equation [8] in conjunction with Equation [9] expresses the essential relation sought for, connecting load capacity with the minimum film thickness h_0 . Although these equations should be credited to Karlson, they have been confirmed by an independent derivation.

To evaluate the factor J/H occurring in Equation [8], we have found it sufficient to plot the integrand of Equation [9] as a function of T for five suitably spaced values of H and to measure the area under each curve. It may be shown analytically that $J/H = 2$ when $H = 0$, and that for perfectly rigid teeth, the maximum pressure p_m is infinite when $H = 0.770$. Thus by dif-

ferentiating Equation [4], the maximum pressure is found to occur when T equals $1/\sqrt{3}$. It is then given by

$$p_m = k \left(\frac{1}{1 - \frac{3}{4} \sqrt{3} H} - 1 \right) \quad [10]$$

which becomes infinite when $H = 4\sqrt{3}/9$, or approximately 0.77. The values of J/H so obtained are recorded in Table 1, and plotted against H in Fig. 1.

NOTE: H and J are dimensionless; see Equations [7] and [9].

FIG. 1 PLOT OF VALUES FOUND BY GRAPHICAL INTEGRATION

To convert F_n values into the component F of tooth load per unit width acting tangentially to the pitch circle, which will be needed for computing the torque on the drive shaft, a factor C_0 , depending on the gear geometry, must be introduced, such that

$$F = C_0 F_n \quad [11]$$

where

$$C_0 \equiv k_0 L_e \cos \alpha \quad [12]$$

Here k_0 is the ratio of the average supporting action of the film at all tooth positions to its value F_n for the pitch-point phase; L_e is the average number of pairs of teeth meshing simultaneously, which governs the effective length of contact; and α the pressure angle. Gatcombe in the reference cited gave values for these constants applicable to a gear and pinion having a 5:1 reduction ratio with 24 teeth in the pinion, and to a rack and pinion described in the *Engineering* article (1) with 54 teeth in the pinion. The values of C_0 ranged from about 1.26 to 1.50.

CALCULATION OF FILM THICKNESS

Eliminating F_n between Equations [8] and [11], we obtain

for the relative film thickness, D being the pinion diameter at the pitch circle

$$\frac{h_0}{D} = C_1 \left(\frac{J}{H} \right) \quad [13]$$

where

$$C_1 \equiv \frac{2 C_0 Z_1 U r}{F D} \quad [14]$$

To find the correct value of J/H for use in Equation [13], we may solve Equation [7] for h_0 and substitute the expression so obtained into Equation [13], after which the resulting equation may be solved for J/H , giving

$$\frac{J}{H} = \frac{C_2}{H^{2/3}} \quad [15]$$

where

$$C_2 \equiv \frac{\sqrt[3]{2r}}{C_1 D} \left(\frac{Z_1 U}{k} \right)^{3/2} \quad [16]$$

Thus for any value of C_2 , representing the data of a given problem, we may plot the graph of Equation [15] in Fig. 1, or such portion as may be required to locate the intersection point. The ordinate of this point is the desired value of J/H .

It is more convenient in practice to express F in terms of P , the load per unit of projected area, this area being arbitrarily chosen as the product of the face width into the pitch diameter of the pinion. Thus

$$F \equiv P D \quad [17]$$

Similarly, it is more convenient to express U in terms of the pinion speed, or number of revolutions per unit time N . At the pitch point $U = U_1 = U_2$, where U_1 and U_2 are the tangential velocities of the tooth surfaces of pinion and gear, respectively. The effects of variations from pitch-point contact are included in the factor C_0 as shown briefly by Gatecombe (3), although a more complete exposition would be reassuring. If now ω_1 and r_1 denote, respectively, the angular velocity of the pinion tooth and its radius of curvature at the pitch point, it follows from the reference cited that U is equal to $\omega_1 r_1$. But ω_1 equals $2\pi N$, therefore

$$U = 2\pi N r_1 \quad [18]$$

Making these substitutions, the working constants become

$$C_1 = \frac{4\pi C_0 r_1 r}{D^2} \left(\frac{Z_1 N}{P} \right) \quad [19]$$

and

$$C_2 = \frac{\pi^{-1/2}}{2 C_0} \cdot \frac{D}{r_1^{1/2} r^{2/3}} \left(\frac{P}{k} \right)^{2/3} \left(\frac{Z_1 N}{P} \right)^{-1/2} \quad [20]$$

CONSTANTS OF THE LUBRICATING OIL

Evaluating Z_1 , the viscosity at atmospheric pressure, offers no difficulty aside from determining the mean effective equivalent film temperature, which has been assumed uniform—an important problem outside the scope of this paper. Evaluating Karlson's constant k requires an experimental knowledge of the viscosity-pressure curve for the lubricating oil at the temperature in question.

When the logarithm of the relative viscosity Z/Z_1 is plotted

against the gage pressure p at constant temperature, the graphs for most lubricating oils are by no means straight lines. They are commonly convex upward and can only be fitted by straight lines for a short interval near the origin, after which they bend over conspicuously. Karlson's equation takes account of this fact. From Equation [1] it will be seen that the logarithm of Z/Z_1 equals twice the logarithm of $(p+k)/k$ and approaches direct proportionality to the logarithm of p/k as the pressure approaches infinity. However, the graph of Karlson's equation falls somewhat below the true curve for the usual lubricating oil, just as the graph of Equation [2] falls too high, assuming that all three graphs have the same slope at the origin. This difficulty can be corrected to a first approximation by assigning a suitable value to the constant k , such that the graph will start out too steep, intersect the true curve near the middle of its pressure range, and drop below it at the high-pressure end, averaging about right.

Let b denote the pressure coefficient of viscosity at atmospheric pressure, elsewhere frequently denoted by b_1 . The pressure coefficient is the relative or fractional increase in viscosity per unit increase of pressure. Its value at atmospheric pressure is equal to the initial slope of the curve obtained when the natural logarithm of the viscosity is plotted against the pressure; and it may be taken equal to 2.30 times this slope when the common logarithm is plotted. Upon differentiating Equation [1], it will be seen that b is equal to $2/k$, from which

$$k = \frac{2}{b} \quad [21]$$

Now let b_0 denote the observed value of the initial pressure coefficient while b is the adjusted, or raised value, corresponding to the desired effective value of k . The adjustment ratio b/b_0 will evidently be greater, the greater the range of pressure over which a fit is required. A perfect fit at the origin would be obtained when b/b_0 equals unity. The corresponding value of k for use in Equation [1] is given by

$$k = \frac{2/b}{b/b_0} \quad [22]$$

Values of the adjustment ratio b/b_0 for two representative lubricating oils are plotted in Fig. 2 as a function of p_m , the maximum film pressure expected. These values were found by a trial fitting of Karlson's formula to the curves for petroleum oil 42 at 77 and 212 F, and castor oil at 167 F, given by Hersey and Hopkins in their paper of 1945 (4), Fig. 4. This fitting should be extended to a wider variety of oils and to higher temperatures. Equation [22] has been plotted in Fig. 3.

NUMERICAL EXAMPLES

In Tables 2 and 3 are given the results obtained by Equations [13], [15], [19], and [20], and associated procedure, for the five problems which had been solved in Gatecombe's paper (3). It is surprising what close agreement is found, considering (a) that the accuracy of his integration has been questioned, (b) that the viscosity-pressure relations used in his paper are based on a straight-line logarithmic equation, and (c) that our own adjustments for evaluating the viscosity constants are far from precise.

The symbols appearing in the tables have all been defined previously except for the abbreviations of units, most of which are familiar. The abbreviation m following the viscosity Z_1 refers to the millionth part of the pound-second per square inch, a convenient unit coming into more frequent use, equal to approximately 6.9 centipoises. This abbreviation is again employed in tabulating the values of $Z_1 N/P$, which are 60×10^4

FIG. 2 ADJUSTMENT RATIO FOR PRESSURE COEFFICIENT

times as great as the values required for use in theoretical equations like [19] and [20].

In Table 3 the first two columns of h_0/D values are, respectively, those computed by Professor Gatcombe in the paper cited, and by the present authors, as explained in footnotes *a* and *b* of the table. The third column contains the limiting values for the imaginary case of zero-pressure coefficient, computed from Equation [13] with J/H set equal to 2.0, which is the value corresponding to $H = 0$ or $k = \infty$ in Equation [7]. The value 9.1 microinches per in. in problem No. 5 is recorded for comparison with the value 8.9 reported by *Engineering*. Finally, in the last column of Table 3 the influence of pressure on viscosity is plainly shown by tabulating the ratio of the film thickness, calculated for a given pressure coefficient, to that calculated for a zero coefficient this ratio varying from approximately 1 to 10.

FIG. 3 KARLSON'S CONSTANT AND OBSERVED PRESSURE COEFFICIENT

FILM-THICKNESS CHARTS

Under the basic assumptions stated, dimensional analysis shows that the relative thickness h_0/D for geometrically similar pairs of gears can be plotted against the operating variable $Z_1 N/P$ and represented completely by a single family of curves, each identified by a constant value of one dimensionless parameter, provided the viscosity-pressure curve can be represented by an empirical equation containing only one constant besides Z_1 . Both Equations [1] and [2] satisfy this condition. When Equation [2] is chosen, and δ replaced by its equivalent $b_0/2.3$, the required parameter turns out to be $b_0 P$. Such a chart was given by Hersey and Hopkins in Fig. 2 of their paper (4), the notation $b_1 P$ then being used, and its value recorded as a percentage.

A chart of the same general type is now given in Fig. 4 using the parameter k/P based on Equation [2]. The value of k required in the application of this chart is that providing the best

FIG. 4 FILM THICKNESS IN GEOMETRICALLY SIMILAR GEARS

fit of Karlson's formula to the experimental viscosity-pressure curve. Figs. 2 and 3 have been offered as a tentative guide in evaluating k until more systematic information can be made available.

The three curves labeled $k/P = 50, 100$, and 200 , were computed from Equations [13], [15], [19], and [20], and Fig. 1, without the aid of Figs. 2 and 3. These latter diagrams are called for only in the application, not in the construction of Fig. 4. The straight graph, identified by $k/P = \infty$, was constructed from Equation [13] in the special form corresponding to $H = 0$, namely

$$\frac{h_0}{D} = \frac{8\pi C_0 r_1}{D^3} \left(\frac{Z_1 N}{P} \right) \dots \dots \dots [23]$$

Equation [23] is equivalent to an equation published by Karlson (2), connecting the film thickness h_0 with the normal tooth load F_n . The small diagram in the upper corner of Fig. 4 shows on a compressed scale the corresponding graph for the rack and pinion described in *Engineering* (1), together with an isolated point representing our solution of problem No. 5. The h_0/D values computed for Table 3 fall exactly into place on Fig. 4 and might have been determined directly from the chart by interpolation.

The main family of curves in Fig. 4 should be found applicable not only to the gear and pinion described, but to any pair geometrically similar to these, regardless of absolute size; and to any lubricant following Karlson's equation, regardless of absolute viscosity. Moreover, it should be possible from the calculations developed in this paper to construct the appropriate charts for any pair of spur gears operating in accordance with the basic assumptions outlined. From an intercomparison of such charts the influence of the purely geometrical factors might be more clearly brought out.

ACKNOWLEDGMENTS

This brief study was undertaken as part of a survey of gear lubrication requested by the Bureau of Ships, Navy Department. The authors are indebted to Mr. H. Blok of Delft, Holland, and

to Prof. E. K. Gatzcombe of the U. S. Naval Post Graduate School, and to the ASME Research Committee on Lubrication, for information and comments that have been helpful in formulating the problem to be solved.

NOTATION

The following notation is used in the paper:

- C_0 = dimensionless constant depending only on the gear geometry; defined by Equation [12]
- C_1 = dimensionless constant defined by Equation [14]
- C_2 = dimensionless constant defined by Equation [16]
- D = pinion pitch diameter
- F = component of F_n tangential to pitch circle
- F_n = normal force on tooth per unit of face width due to film pressure
- H = dimensionless quantity proportional to $Z_1 U/k$ and depending also on film thickness; defined by Equation [7]
- J = dimensionless quantity proportional to tooth load; defined as a function of H in Equation [19].
- L_e = average number of teeth meshing simultaneously
- N = pinion speed in revolutions per unit time
- P = tooth load per unit of projected area formed by face width multiplied by pitch diameter; or ratio F/D , Equation [17]
- T = ratio of distance along tooth profile to square root of $2rh_0$, defined by Equation [5]
- U = mean of U_1 and U_2
- U_1 = tangential velocity of pinion-tooth surface
- U_2 = tangential velocity of gear-tooth surface
- Z = viscosity of lubricant at any point in film, as affected by pressure and temperature
- Z_1 = viscosity at atmospheric pressure but at temperature of film
- b = pressure coefficient of viscosity at atmospheric pressure, evaluated for optimum fit between theoretical and observed viscosity-pressure curves
- b_0 = observed pressure coefficient at atmospheric pressure
- h_0 = film thickness at point of nearest approach, also called minimum film thickness
- k = empirical constant in Karlson's parabola, Equation [1], expressing the viscosity-pressure relation
- k_0 = ratio of average F_n for all contact phases to value of F_n for contact at pitch point
- p = fluid pressure at any point in film as a function of x or T
- p_m = maximum value of p

- r = effective contact radius defined by Equation [6]
 r_1 = radius of curvature of pinion tooth at contact point
 r_2 = corresponding radius of curvature of gear tooth
 x = distance along tooth profile from point of nearest approach, considered positive in the direction of motion
 α = pressure angle fixed by gear geometry
 δ = empirical constant in Equation [2] proportional to pressure coefficient of viscosity
 π = as usual, 3.1416
 ω_1 = angular velocity of pinion

Discussion

H. Blok.* The paper touches upon the following important question, which forms the background to the present discussion: What are the limits inherent in the hydrodynamic lubrication of straight spur gears? Under the authors' five basic assumptions the answer doubtless is: There are no such limits, if viscosity increases quadratically with pressure according to Karlson's parabolic Equation [1]. This can easily be verified by referring to the critical cases, that is, the limiting cases where maximum oil pressure p_m becomes infinitely high (H assumes its critical value $4/3\sqrt{3} = 0.770$, as indicated by Expression [10], where H is defined by Equation [7]). In fact, it was shown by the authors that in the critical cases hydrodynamic load capacity F_n , as expressed by Equations [8] and [9], will become infinite. In this connection it is noteworthy that, in any given spur gear (given effective contact radius r ; see [7]) for any given atmospheric viscosity Z_1 , velocity U , and tolerable minimum film thickness h_0 , the critical value of H can in principle always be reached by proper choice of the empirical oil constant k , that is, of the oil. This indeed leads to the conclusion that, as long as all of the authors' basic assumptions as well as Karlson's viscosity-pressure relationship can be upheld, hydrodynamic load capacity in principle is unlimited.

It remains to be seen whether or not the basic assumptions and Karlson's relationship can be upheld, when the critical cases are approached.

In so far as Karlson's relationship is concerned, this was acknowledged by the authors to break down for the high oil pressures involved in the cases contemplated. Then, the following generalized viscosity-pressure relationship would have to be substituted for Karlson's

$$Z = Z_1(1 + p/k)^n \quad [24]$$

where n would be greater than 2; particularly, the higher the maximum oil pressure to be accounted for, the higher would n have to be.

With the foregoing generalized relationship, it is found that the critical cases, where maximum oil pressure becomes infinitely high, occur when the quantity H (see Expression [7]) becomes equal to its critical value H_c .

$$H_c = 4/3\sqrt{3}(n-1) \quad [25]$$

For instance, for $n = 8$, which the authors found to hold good for castor oil, H_c would amount to $4/21\sqrt{3} = 0.110$.

Further, it proves that, in contrast with $n = 2$ as in the paper (or more generally, $n \leq 3$), as soon as n is greater than 3; hydrodynamic load capacity in the critical cases no longer becomes infinitely high, but remains finite, notwithstanding that maximum

oil pressure continues to be infinitely high.⁵ This can be shown in the following way:

With Equation [24] instead of Karlson's relationship, Equation [1] of the paper, it can easily be deduced that the distribution of oil pressure p in the film, as a function of the variable T , is given by

$$p = k \left[\left\{ 1 - (n-1) \cdot H \cdot 4T / (1 + T^2)^2 \right\}^{-\frac{1}{n-1}} - 1 \right] \quad [26]$$

so that maximum pressure p_{max} , which occurs in the film section defined by $T = 1/\sqrt{3}$, is

$$p_{max} = k \left[\left\{ 1 - (n-1) \cdot \frac{3\sqrt{3}}{4} \cdot H \right\}^{-\frac{1}{n-1}} - 1 \right] \quad [27]$$

In fact, for $n = 2$, Equation [26] reduces to the authors' Equation [10] and, for $H = H_c$ (compare Equation [25]), p_{max} becomes infinitely high.

With Equation [26], instead of the authors' Equation [8], we now arrive at the more general expression for hydrodynamic load capacity F_n (compare Equation [3] of the paper):

$$F_n = \frac{2Z_1 U r}{h_0} \cdot \left(\frac{J_n}{H} \right) \quad [28]$$

where J_n represents the integral

$$J_n = \int_0^\infty \left[\left\{ 1 - \frac{16}{3\sqrt{3}} \cdot \frac{H}{H_c} \cdot \frac{T}{(1 + T^2)^2} \right\}^{-\frac{1}{n-1}} - 1 \right] dT \quad [29]$$

For the critical cases $H = H_c$, it now follows from analytical inspection of the singularity then occurring in the integrand of Equation [29] at $T = 1/\sqrt{3}$, that, in fact, as soon as $n > 3$, hydrodynamic load capacity remains finite, as then the Integral [29] converges.

By numerical evaluation it was found that for $n = 4$ and 6, in the critical cases $H = H_c$, the factor J_n/H amounts, respectively, to 11.9 and 7.25; this means that in these critical cases, the relative gains in hydrodynamic load capacity, as compared with the classical case where viscosity is assumed to be independent of oil pressure, are 5.95 and 3.63.⁶ It can be shown that at increasing values of n the critical J_n/H from Integral [29] monotonously decreases toward an asymptotic limit; this could be checked if the authors would communicate the critical value of the integral, Equation [29], that they computed for their value of $n = 8$.

Thus it would appear that with $n > 3$ the generalized viscosity-pressure relationship, Equation [24], in fact, results in a gain in hydrodynamic load capacity; this in contradistinction to the authors' case $n = 2$, where the gain is infinitely great. In this respect it should be noted that values of n greater than 3 (such as 8) are more representative of actual lubricating oils than the originally proposed value $n = 2$. Let us consider this point further in the light of the theory by Gatecombe,⁷ who used the same basic assumptions as the authors, but based his calculations on a viscosity-pressure relationship different from Equations [1] and [24],

⁵ By utilizing the method worked out by W. Weibull in his paper: "Glidlager teori med variabel Viskositet" (Theory of Slider Bearings With Variable Viscosity) in the Swedish journal *Teknisk Tidskrift, Mekanik*, vol. 55 (1925), pp. 164-167, it can also be shown that, if in Equation [24] the exponent n is smaller than unity, there are no critical cases at all; in other words, maximum oil pressure then could never become infinitely high.

⁶ It should be noted that for pressure-independent viscosity—the factor J_n/H from Equation [28] assumes the value 2.

⁷ Reference is to author's Bibliography (3).

* Senior Research Engineer, Koninklijke/Shell-Laboratorium, Delft, Holland.

that is, on the exponential relationship Equation [2] of the paper.

Now, the authors themselves have already compared Gatecombe's results with theirs (Table 3), but, as Gatecombe had not been able to evaluate his theory in an exact analytical way, for their purpose the authors had to confine themselves to Gatecombe's "approximate" evaluation. However, it can be shown by the following arguments that the approximation involved is no longer tolerable when a critical case is approached.

Gatecombe's exact result can be written in the form of Equation [28], if the numerical factor (J_n/H) is replaced by B

$$B = -\frac{1}{A} \int_0^{\pi} \ln[1 - A(\sin 2S + \frac{1}{2} \sin 4S)] \cdot \sec^2 S \cdot dS \quad [30]$$

where the nondimensional quantity A is defined by

$$A = \frac{1}{12} G \delta \ln 10 \quad [31]$$

if Gatecombe's notation is upheld, or, if rewritten in the authors' notation by

$$A = Z_1 U (2r)^{1/2} \cdot h_0^{-3/2} \delta \ln 10 \quad [32]$$

Gatecombe's approximation amounts to the same thing, as replacing the exact value of B Integral [30] by the approximate one

$$B \approx \frac{\pi}{120} \cdot \left[4\pi \ln 10 - \frac{27}{A} \cdot \ln \left(1 - \frac{3\sqrt{3}}{4} A \right) \right] \quad [33]$$

As was shown by Gatecombe, with the exponential viscosity-pressure relationship, Equation [2] of the paper, critical cases arise, that is, maximum pressure theoretically becomes infinitely high, when A becomes equal to its critical value⁸ of $4/3\sqrt{3}$.

Whereas, for the critical value of A , the integrand of Integral [30] shows a singularity at $S = \pi/6$, it can be shown by analytical inspection that yet this integral converges, so that the corresponding value of B or, say, hydrodynamic load capacity remains finite in the critical cases. On the other hand, Gatecombe's approximate value for B (see Expression [33]) becomes infinite for the critical value of A . This proves that, in fact, Gatecombe's approximation is no longer tolerable when a critical case is reached or approached.

In view of the background to the present discussion, we are left with the problem of computing, from Integral [30], a workable expression for B that is applicable at least to the critical and the near critical cases. Fortunately, it proves that an exact evaluation of the integral of Equation [30] is possible, so that this evaluation is even applicable to the whole physically significant range $0 \leq A \leq 4/3\sqrt{3}$. The method of exact evaluation found will now be elucidated, the more so as it is also applicable to the authors' Integral [9].

Changing to the authors' variable T , and partially integrating Integral [30], it is easily found that

$$B = 12 \int_0^{\infty} \frac{TdT}{(1+T^2)^3 - 4.4T} - 16 \int_0^{\infty} \frac{TdT}{(1+T^2)[(1+T^2)^2 - 4.4T]} \quad [34]$$

The foregoing two integrals can, in fact, be evaluated in terms of elementary functions by observing that the integrands can be re-

solved into partial fractions of no higher than the second degree, namely, as follows:

According to Descartes' well-known method of solving biquadratic equations, the form $[(1+T^2)^2 - 4.4T]$ can be resolved into the product of two quadratic forms

$$(1+T^2)^2 - 4.4T = (T^2 - uT + v)(T^2 + uT + w) \quad [35]$$

where u , v , and w are determined, for any given A , by the positive root of Descartes' "cubic resolvent"⁹

$$y^3 + 4y^2 - 16A^2 = 0 \quad [36]$$

That is, u , v , and w follow consecutively from the formulas

$$u = \sqrt{y} \quad [37a]$$

$$v = \frac{1}{2} (2 + y - 4A/\sqrt{y}) = \frac{1}{2} (2 + u^2 - 4A/u) \quad [37b]$$

$$w = \frac{1}{2} (2 + y + 4A/\sqrt{y}) = \frac{1}{2} (2 + u^2 + 4A/u) \quad [37c]$$

In this way, the integrals in Equation [34] were actually evaluated in an exact analytical way. As, however, for an arbitrary value of A , within the range $0 \leq A \leq 4/3\sqrt{3}$ to be considered, the expression for B is rather unwieldy, the expression for the critical case only of $A = 4/3\sqrt{3}$ will be given here, namely

$$B = \frac{3}{2} \cdot [(\sqrt{3} - \sqrt{2}) \cdot \pi + \ln 3 + 2\sqrt{2} \cdot \tan^{-1} (2\sqrt{2})^{-1}] = 4.588 \quad [38]$$

Thus we arrive at the conclusion that, with the exponential viscosity-pressure relationship Equation [2] of the paper, in the critical cases hydrodynamic load capacity is only $4.588/2 = 2.294$ times as high as it would be when viscosity is constant, that is, not affected by pressure. This entails, of course, that Gatecombe's approximation can no longer be upheld in those cases where it predicts a relative gain (called "pressure effect," in the last column of the authors' Table 3) in hydrodynamic load capacity that is greater than 2.294. Such cases are represented by Gatecombe's problems Nos. 1, 2, and 4; thus only to problems Nos. 3 and 5 can some significance be attached for the authors' purpose of comparing their results with Gatecombe's.

So far, the authors' and Gatecombe's basic assumptions have been upheld; it remains to be seen, however, whether these assumptions are permissible, and if not sufficiently so, when they will break down. Here we shall solely consider the question of the validity of the assumption about the perfect rigidity of the mating tooth faces. The reason that it can be made acceptable is that only the elastic distortion of the tooth faces, such as actually occurs when oil pressures in the film are sufficiently high,¹⁰ can, in conjunction with the increase in viscosity with pressure, contribute substantially to hydrodynamic load capacity; thus we might arrive at an explanation of the remarkable fact that in practice there are many cases of gears where hydrodynamic load capacity obviously is very much greater than would be predicted by Martin's anonymous paper (1)¹¹ on the elementary theory of hydrodynamic lubrication of gear teeth.

It will be evident that tooth faces may no longer be considered

⁸ It is easily demonstrated that, for $0 \leq A \leq 4/3\sqrt{3}$, which is the physically significant range of A , the cubic Equation [36] has one positive root only.

¹⁰ The type of elastic distortion meant here was called "hydrodynamic depression" in the present writer's paper: "Fundamental Mechanical Aspects of Thin-Film Lubrication," (read on March 4, 1950, before the New York Academy of Sciences); in this paper further particulars about the relevant gain in hydrodynamic load capacity can be found.

¹¹ Reference is to authors' Bibliography (1).

⁹ By sheer coincidence the critical value for A happens to be the same as the one for the authors' H in their case of $n = 2$.

to be perfectly rigid in those cases where the maximum film pressure, as calculated by the theory to be checked, attains or exceeds the order of magnitude of the Hertzian contact pressure that would obtain for the load considered if there were no oil film at all. In fact, in such cases the elastic distortions of the tooth faces under the high oil pressures must be comparable with those according to the Hertzian theory of elastic contact. This means, however, that, with the small minimum film thicknesses involved, the geometry of the film, and thereby the distribution of film pressures and hence the corresponding hydrodynamic load capacity, must be altered appreciably. Examples of the foregoing cases are provided by all of Gatecombe's problems, except No. 5 (compare the authors' Table 3).

It would also appear that the somewhat disturbing critical cases with their infinitely high maximum oil pressures would disappear automatically when the elastic distortions of the tooth faces are taken into account. Anyway, in cases representative of the beneficial effects on hydrodynamic load capacity of the increase of viscosity with pressure, the additional beneficial effects of the elastic distortions mentioned have to be accounted for simultaneously. Of course this renders the computer's task much more difficult; however, some headway has already been made and it is hoped that the results can be published in the not too distant future.

AUTHORS' CLOSURE

It is reassuring to have Mr. Blok's opinion that the effect of elastic deformation is to increase the film thickness. This confirms the authors' belief that the assumption of rigid teeth gives film thickness values on the safe side, the true values being greater than calculated. It was not the authors' desire to defend that assumption but only to treat it as a limiting case. Let us hope that new investigations will soon be available in which elastic deformation is combined with hydrodynamic action. Meldahl¹² took a long step in this direction but did not include the viscosity-pressure effect.

Mr. Blok offers constructive comment in two principal directions: first, by explaining the question he had raised (5) regarding the accuracy of Gatecombe's theory, and providing an exact analytical solution; second, by outlining a solution for rigid teeth based on a more general form of the viscosity-pressure relation, namely Equation [24].

This equation is a fairly obvious generalization of Karlson's parabola, the only change being the substitution of an empirical exponent n in place of the parabolic exponent 2. The same generalization had also been investigated by the authors, and the main results stated during the oral presentation of the paper. These are summarized below in response to Mr. Blok's inquiry regarding the critical value of the load integral in Equation [29] when $n = 8$.

Proceeding as in Karlson's paper except for the use of n in place of 2, the authors had arrived at relations identical with Equations [26] to [29] by completely analytical steps. Equation [29] was then integrated graphically for chosen values of H , leading to the round number $J_n/H = 6$ when $n = 8$ and H has the critical value $H_c = 0.110$. An analytical proof that the load integral remains finite in the critical case if n is greater than 3 had been given by Mr. Lowdenslager.

A more precise solution was then made in which the area under the pressure curve was evaluated by a semianalytical method.

¹² "Contribution to the Theory of the Lubrication of Gears and of the Stressing of the Lubricated Flanks of Gear Teeth," by A. Meldahl, *Brown Boveri Review*, vol. 28, 1941, pp. 374-382.

The tail of the diagram from T_1 to infinity, where T_1 is large compared to the value T_0 at which the formula gives infinite pressure, was computed by treating T_0/T as a negligible quantity. The peak area was evaluated by neglecting $T-T_0$ in comparison with T_0 , using a factored expression kindly suggested by Prof. J. T. Burwell, Jr., of M.I.T. The mean of both methods gave $J_n/H_c = 6.2$. This is in good agreement with a more exact value, 6.23, communicated by Mr. Blok. In fact, Mr. Blok and the authors, working independently, arrived at similar conclusions on every essential aspect of the problem.

All the values found for J_n/H_c are plotted in Fig. 5 as a function of n . Fig. 6 has been constructed with the aid of Fig. 5 and can be offered as a tentative generalization of Fig. 1. In Fig. 6 the dashed curves for $n = 3, 4, 6$, and 12 have been drawn in free-hand from $H = 0$ to their known end-points corresponding to $H_c = 0.384, 0.257, 0.154$, and 0.070 respectively, and faired by cross-plotting of H against n at constant values of the ordinate.

From Fig. 6 and its future refinements, in conjunction with Equations [13], [15], [19], and [20] of the paper it should be possible to generalize the film-thickness chart, Fig. 4, for all values of n . In the meantime, the practical use of Fig. 4, with Karlson's exponent 2, requires only that suitable values be selected for the empirical constant k with the aid of Fig. 3, as described in the paper.

Thermal-Shock and Other Comparison Tests of Austenitic and Ferritic Steels for Main Steam Piping

By W. C. STEWART¹ AND W. G. SCHREITZ,¹ ANNAPOLIS, MD.

Thermal-shock tests of 6-in. pipe-and-valve assemblies, representing both austenitic and ferritic steels in 80 and 160 schedules, are described. The shock-testing procedure was devised to simulate conditions resulting from carry-over of boiler feedwater into main steam lines operating at 900 or 2000 psi pressure, 1050 F temperature. Other test procedures described include cyclic deflection tests of full-size mock-ups consisting of 160 schedule pipe and valves for simulating expansion bends. Results are reported for mock-ups of both austenitic and ferritic materials which were tested at 2000 psi pressure, 1050 F temperature. Each assembly was subjected to 4000 or more deflections corresponding to expansion cycles that would obtain on heating up a piping system from room temperature to 1050 F once every 2 days for approximately 20 years.

INTRODUCTION

DECISION to investigate the feasibility of utilizing 18-8 chromium-nickel-type steel for main steam piping for 1050 F temperature service was prompted by the superior strength properties of the material at temperatures above 1000 F. Moreover, the superior high-temperature properties of the austenitic steels over the ferritic steels for temperatures above 1000 F are reflected in the higher working stresses allowed by the ASME Boiler Code. The higher working stresses for austenitic steel should permit the use of thinner and lighter pipe which, at the higher pressures, is particularly advantageous from the standpoint of increased flexibility and weight saving. On the other hand, thermal expansion is greater for austenitic steel than for ferritic steel, and this fact must not be overlooked in considering flexibility factors.

No experience with austenitic steel for main steam piping has been reported, although the material has been used for boiler feed lines. H. Weisberg² has reported on cyclic heating tests of main steam-piping joints between ferritic and austenitic steels. Reports from the oil industry of failures of components in pipe lines used to convey charges of hot oil from cracking stills created doubt as to the suitability of austenitic steel for main steam piping.

It is reported that components in austenitic-steel pipe lines have shown much greater susceptibility to cracking as a result of thermal shock produced by the periodic flow of hot oil than have similar components of ferritic-steel pipe lines. In view of this

information it did not seem unreasonable to assume that austenitic steel might exhibit similar susceptibility in steam service under conditions of thermal shock occasioned by boiler-water carry-over. Moreover, experience has been cited which indicates strength deficiencies for austenitic-steel castings as well as for welded joints between austenitic pipe and castings.

There are numerous points of difference between pipes carrying hot oil as previously mentioned and main steam lines. In the case of oil pipe lines, the pressures are fairly low and the temperature of the oil high. For steam lines under consideration the pressure is high and the temperature intermediate by comparison. In the oil pipe lines conditions producing high thermal gradients recur regularly, while conditions producing similar gradients in steam lines occur only infrequently as a result of boiler-water carry-over. Then, there is the difference in heat-transfer characteristics for the two processes which appears to be an important factor in favor of steam applications. Hot oil on passing through a relatively cold pipe causes the inside layer to expand. This expansion is resisted by the colder outer layers with the result that the inside is stressed in compression. Cracking occurs on cooling when the inside of the pipe is in tension.

The introduction of a quantity of boiler water along with the steam flow cools the inside surface, producing a thermal gradient in the pipe wall. Contraction of the quenched layer is resisted by the outer layers of the pipe which are at higher temperature, with the result that the inside of the pipe is subjected to a tensile stress. Therefore any tendency to cracking in steam pipes under thermal shock associated with feedwater carry-over would be expected to occur on quenching.

In setting up the test program, it was decided to subject full-scale pipe-and-valve assemblies to thermal-shock conditions simulating boiler-water carry-over. It was reasoned that this procedure would produce the maximum temperature gradient in the pipe wall that could be expected in service. A second series of tests included in the program consisted of subjecting full-scale mock-ups to deflection cycles designed to simulate stress conditions produced in expansion loops on heating and cooling. At the outset, it was the intention to test only the austenitic material under thermal shock. Later, it was decided to conduct parallel tests of 2 $\frac{1}{4}$ Cr-1 Mo steel throughout.

In order that information on the strength properties of the particular test materials might be available, a laboratory test program was included as a phase of the investigation. Specimens for this purpose were fabricated from sections of 6-in., 80, and 160-schedule pipes and cast cylinders designed to simulate cast valve bodies. The same welding procedures were employed in fabricating these test sections as were used in welding the thermal-shock assemblies and mock-ups.

Welding of the original test assemblies, including the specimens for the laboratory test program, was performed by a large commercial fabricator utilizing production welding practices with regard to qualification of welders, number of welders employed on the job, shift work, and extent of supervision exercised over the welders.

DESCRIPTION OF THERMAL-SHOCK TEST ASSEMBLIES

Details of the thermal-shock test assemblies are shown in Fig. 1. Four 6-in. assemblies are shown. Two are of austenitic steel, type 347, in 80 and 160 schedules, and the other two ferritic steel, Type T-22 in the same schedules. The lighter assemblies were prepared for testing at 900 psi pressure, 1050 F temperature, and the heavier specimens for testing at the same temperature, but at 2000 psi pressure. Each assembly contains two pressure-seal bonnet gate valves, one of cast material and the other of forged material, both of similar composition to the pipe. The 160 schedule austenitic assembly contains a 36-in. length of 2½ Cr-1 Mo steel pipe at mid-length, while the ferritic assembly contains a similar length of austenitic-steel pipe. This arrangement permitted the simultaneous testing of joints between the dissimilar steels. In the austenitic assembly a transition type of welded joint was employed, while the dissimilar materials in the ferritic assembly were joined by means of V-type welds. Details of the transition-type joint are given in Fig. 1. No dissimilar metal sections were incorporated in the 80-schedule thermal-shock assemblies.

Fig. 2 shows the design of the V-type weld employed in welding the thermal-shock assemblies. The welds of the ferritic-steel assemblies, except for the welds joining the dissimilar pipe section, were made with 2½ Cr-1 Mo electrodes. The dissimilar pipes were welded with 25-20 chromium-nickel electrodes. The V-welds of the austenitic assemblies are of two types, those made with 19-9 Cb electrodes and those made with 25-20 electrodes as indicated in Fig. 1.

FIG. 2 DETAILS OF V-TYPE WELDED JOINT

The 2½ Cr-1 Mo steel pipe is in accordance with ASTM A158-46T, except that chemical requirements are as per ASTM Specification A213-46T for Grade T-22.

The prescribed welding procedure included the following:

All joints of 2½ Cr-1 Mo steel were preheated to a minimum temperature of 400 F for welding, and this temperature was maintained until final heat-treatment was accomplished. After welding and while the interpass temperature was held, a circumferential band on each side of the weld, having a width of not less than 6 times the section thickness of the pipe, was heated uniformly to a temperature within the range 1325-1350 F. The zone was maintained at this temperature for a period of time equivalent to 2 hr per in. of thickness. Retarded rates of cooling were employed.

The 18-8 Cb pipe is in accordance with ASTM A158-46T for Grade P8L. The pipe was stabilized at 1550 F temperature as a final operation, pickled, plus all supplementary requirements of specification. No preheat or postheat was employed in welding the austenitic-steel pipe.

The material for the cast austenitic-steel valve bodies is in

accordance with ASTM Specification A157, Grade C9, except 0.10 per cent maximum carbon and columbium stabilized. Material for the forged austenitic valve bodies is as per AISI Type 347. All bodies were given the following treatment:

Heated to 1850 F minimum, held for 4 hr, and cooled in air blast until black. Stabilizing treatment consisted of heating to 1575-1625 F, holding for 8 hr, and cooling in air.

The material of the cast ferritic-steel valve bodies is as per ASTM Specification A217, Grade WC3. The chemical composition of the forged valves is as per ASTM Specification A213-46T, Grade T-22. The valve bodies were heat-treated as follows:

Cast Bodies:

Normalizing treatment

Heated to 1775-1825 F, held for 4 hr, cooled in air

Air-quench treatment

Heated to 1675-1725 F, held for 4 hr, cooled in air

Tempering treatment

Heated to 1275-1325 F, held for 4 hr, cooled in air

Forged Bodies:

Air-quench treatment

Heated to 1550-1600 F, held for 4 hr, cooled in air

Tempering treatment

Heated to 1275-1325 F, held for 4 hr, cooled in air

Prior to welding, the thermal-shock specimens were drilled for thermocouples as shown in Fig. 3. The thermocouple holes are 0.136-in. diam and are located on the underside of the pipe about 6-in. upstream from the cast valves, where the quenching action would be most severe. The thermocouples are held against the metal at the bottom of the wells by coil springs. Drilling these

FIG. 3 THERMOCOUPLE LOCATION IN PIPE WALL

holes prior to welding permitted more accurate depth measurements to be made. Leads from the thermocouples were connected to jacks mounted in a panel board, and the circuits to the instruments were completed by plugging in on the panel.

Characteristics of the temperature recorders used in the investigation are as follows:

Four-point recorder, chart speed 8 ipm, 0 to 1200 F, minimum time between printed points 1 sec.

Continuous pen recorder, 0 to 1200 F, chart speed 8 ipm, maximum pen speed 4.5 sec for full scale travel.

Continuous pen recorder, double range 0 to 12 mv and 0 to 1200 F. Chart speed 8 ipm, maximum pen speed 2.2 sec for full scale travel.

THERMAL-SHOCK TESTS

The thermal-shock specimens were set up for test as shown in Fig. 4. Steam was supplied from a Bessler boiler and separately fired superheater, and thence through a booster superheater before entering the test assemblies. The temperature of the steam on leaving the Bessler superheater was approximately 930 F. The steam at the outlet of the booster superheater was maintained at 2000 psi pressure, 1065 F temperature, which insured steam at 1050 F at the test assemblies. The flow of steam was maintained constant by means of orifice plates in the discharge lines; about 7500 lb of steam per hr was passed through each assembly. Steam on leaving the assemblies was passed through a desuperheater, thence to a condenser.

As shown in Fig. 4, two thermal-shock specimens of the same

FIG. 4 LAYOUT OF THERMAL-SHOCK TEST SPECIMENS

schedule are arranged in parallel with the quenching tower suspended between them. The tower is provided with four thermocouple wells distributed over its length. Thermocouples placed in these wells indicate the water level in the tower. The test assemblies are mounted on rollers to prevent longitudinal restraint. Thermal shock is produced by introducing water at the saturated temperature into the assemblies after the latter have attained temperature equilibrium. The water is introduced along with the flow of superheated steam in order more nearly to simulate actual service conditions.

The original plan of test called for shocking the austenitic and ferritic assemblies alternately. A few preliminary runs showed that this was impracticable as the procedure caused too much fluctuation on the boiler, and besides, the main valves were difficult to operate with long rods extending outside the protective enclosure. Accordingly, one assembly was tested at a time. The assemblies were shocked with either 60 or 88 lb of water, corresponding to levels 2 and 3 of the quenching tower. The volume of quenching water, whether 60 lb or 88 lb, had no significant effect on the temperature gradients produced in the pipe walls.

A temperature record was taken for each thermal shock, the order of taking thermocouple records being varied so that all combinations of temperature differences would be obtained. For several runs, records were obtained on a multipoint recorder which gave a complete record. However, the printing speed of the multipoint recorder was not sufficient to obtain maximum temperature differentials. Temperature gradients given in the paper represent a composite of several average runs. Readings obtained with a differential recorder were not in good agreement with the corresponding temperature differentials obtained for iron-constantan thermocouples, but the records do serve to confirm a peculiar behavior observed for one of the regular thermocouples. This circumstance will be referred to later in the paper.

Test data obtained for the thermal-shock specimens are given in Table 1.

Temperature of quench water, deg F.....	1050	1050	1050	1050
	533	635	533	635

NOTE: All four thermal-shock assemblies withstood the 100 or more quenching cycles without failure by rupture.

Time-temperature curves for four locations in the pipe walls of the 160-schedule austenitic and ferritic assemblies are shown in Figs. 5 and 6. These assemblies were quenched with water at the saturation temperature (635 F). In Fig. 5 the curve for thermocouple T-1 is shown as crossing the curve for thermocouple T-2 at 16 sec and recrossing at 26 sec. This anomaly was observed only in the case of the austenitic assembly, as will be seen by a comparison of the time-temperature curves in Figs. 5 and 6.

Differential thermocouple readings obtained for the austenitic assembly also indicated a higher temperature for T-1 than for T-2 over a short period of time, thus confirming results obtained with regular thermocouples. Similar differential thermocouple records for the ferritic assembly showed no corresponding

anomalous behavior. Temperature differentials obtained from curves T-1 and T-4 in Figs. 5 and 6 are plotted in Fig. 7. The slow response of thermocouple T-1 of the austenitic assembly on quenching is indicated by the lower portion of the curve. No satisfactory explanation for this behavior is available.

Similar time-temperature curves for the 80-schedule austenitic and ferritic assemblies are shown in Figs. 8 and 9. During these tests, trouble developed in thermocouples T-2 and T-3 of the austenitic assembly, and in T-3 of the ferritic assembly. In view of this, results obtained for these thermocouples are not included in the paper. Temperature differentials for thermocouples T-1 and T-4 of the 80-schedule assemblies as taken from the time-temperature curves in Figs. 8 and 9 are presented in Fig. 10.

STRESS CALCULATIONS

Thermal stresses produced in the 160 schedule assemblies as a result of the quenching action were calculated from Timoshenko's thermoelastic formula. As the temperature was measured at four positions, three positions within the pipe wall and on the outside of the pipe, it was necessary to interpolate to find the temperature at points between the locations where it was actually measured. This interpolation was done under the assumption that the temperature varied linearly between successive readings, from thermocouple to thermocouple. It was possible to find the temperature of the inside wall by extrapolating the values from the first two thermocouples as these were quite near the wall.

The stresses at radii corresponding to the four thermocouples were calculated from four integrals which were added to get the corresponding integral for outside radius to inside radius. As a check the integral from outside radius to inside radius was calculated in a similar manner, assuming that the temperature varied linearly throughout the pipe wall. These yielded values are very near the values as calculated by thermocouple-to-thermocouple integration. The maximal tensile stress developed in each of the assemblies as calculated by this method was about the same, namely, 32,000 psi. The maximal tangential stress was computed using the formula,⁴ developed under the assumption that the temperature varied linearly from wall to wall. Results checked closely with the largest of the stresses computed by the method previously described.

DESCRIPTION OF MOCK-UPS

On completion of the thermal-shock tests of the 160-schedule assemblies, the valves with connecting section of pipe were removed for rewelding in mock-ups for cyclic deflection tests. In sectioning the thermal-shock specimens, one cut was made about 5 in. upstream from the cast valve, and the other 12 in. downstream from the forged valve. A 7-in-long section of pipe was welded to the pipe adjacent to the cast valve to make the assembly symmetrical. Then, S-bends were welded to the ends of the pipe and valve assemblies, producing a mock-up as shown in Fig. 11. The design of these welds differed somewhat from the original welds in that a flat split backing ring with four pins to maintain $\frac{3}{4}$ in. root spacing for the austenitic pipe and $\frac{1}{4}$ in. root spacing for the ferritic pipe was employed.

As shown in Fig. 11, one end of the loop is anchored and the other end pinned to the piston of a hydraulic cylinder having an 8-in. bore. The free end of the loop is restrained from moving in any but the horizontal direction by a 30-in-long sleeve bearing. The hydraulic cylinder is supplied with oil at the rate of 50 cu in. per min by a motor-driven pump. The direction of the piston is reversed by means of an electrically operated four-way valve, the length of the stroke being controlled by microswitches. Three

safety devices are contained in the hydraulic system, i.e., (1) a pressure-relief valve set at 300 psi, (2) a pressure switch adjusted to shut-down the pump when the pressure exceeds 275 psi, and (3) a by-pass valve in a line connecting the ends of the cylinder.

RESULTS OF MOCK-UP TESTS

Deflection tests were made of the 160-schedule mock-ups at room temperature after mounting resistance-type strain gages at a number of locations as indicated in Fig. 11. Readings were taken on all gages after removing the pin from the shackle of the

piston so as to insure a free-end condition. The connecting pin was then replaced without producing appreciable change in the initial readings. Next, 2000-psi hydrostatic pressure was applied to the assembly, and another set of readings taken. Strain-gage readings were obtained for different positions of the piston while compressing the loop. Readings were taken about every 0.3-in. movement of the piston for a total movement of 2 in.

The relationship between deflection and strain or equivalent stress having been established at normal temperature, it was only necessary to multiply the normal temperature deflection by the

FIG. 7 TEMPERATURE DIFFERENCE BETWEEN COUPLES T-1 AND T-4 IN THE 160-SCHEDULE, 6-IN. PIPE ASSEMBLIES DURING QUENCH PERIOD

ratio of moduli of elasticity of the material at normal and 1050 F temperatures to obtain the deflection necessary to produce the corresponding stress at the elevated temperature. For the austenitic steel this ratio is $28.8/23.0 = 1.25$; and for the ferritic steel $30.4/21.0 = 1.45$.

Steam was passed through the mock-up at the rate of 5000 lb per hr, temperature equilibrium at 1050 F temperature being established after 6 hr. The unrestrained position of the free end of the assembly was determined within 0.02 in. In the case of the 160-schedule austenitic mock-up, the stroke was adjusted to produce an equivalent stress of approximately 21,500 psi for

the extreme end of the stroke, and a corresponding stress of 11,500 psi for the opposite end of the stroke, the variable equivalent stress being 10,000 psi. For the 160-schedule ferritic mock-up the corresponding stress range was 15,750 to 9750 psi, and the variable equivalent stress 6000 psi. The stroke and equivalent-stress relationships were based upon strain values obtained for gages e and f as shown in Fig. 11. In taking the strain readings on the ferritic mock-up, a rosette strain gage containing a 45-deg element was placed at location ef. This permitted evaluation of shear stress which was found to be negligible.

The principal stresses computed from the strain-gage readings for the cold condition, including the equivalent stresses, are given in Table 2. The stresses were computed from the following relationships:

$$S_x = \frac{E(\epsilon_x + \mu\epsilon_y)}{1 - \mu^2}$$

$$S_y = \frac{E(\epsilon_y + \mu\epsilon_x)}{1 - \mu^2}$$

$$S = \sqrt{S_x^2 + S_y^2} - S_x S_y$$

where

- S_x = longitudinal stress, psi
- S_y = circumferential stress, psi
- S = equivalent stress, psi
- ϵ_x = unit strain in x-direction
- ϵ_y = unit strain in y-direction
- μ = Poisson's ratio = 0.3

In setting up the test procedure for the mock-ups, it was decided to subject the members to 4000 deflection cycles. This number of cycles was selected as representing the contraction and expansion that a piping system would undergo if brought up to 1050 F from normal temperature once every 2 days for approximately 20 years.

The 160-schedule austenitic mock-up was subjected to 4100 deflection cycles, and the corresponding ferritic mock-up to 4300 cycles. Neither mock-up showed any effect of the test which could be discerned by the operating personnel. The average inlet and outlet steam temperatures for the austenitic assembly were 1055 F and 1045 F. The corresponding temperatures for the

(a) Values for maximum inward deflection of loop.

(b) Values for minimum inward deflection of loop.

ferritic mock-up were 1057 F and 1048 F. The austenitic mock-up was under test approximately 135 hr at 30.4 cycles per hr. The ferritic mock-up was under test 116 hr at 37 cycles per hr.

The next phase of the investigation will consist of similar tests of the 80-schedule mock-ups.

Following the cyclic deflection tests, zero points for the free-end condition were determined. The zero point of the free end of the austenitic assembly after 4100 deflection cycles indicated that the assembly was 0.44 in. shorter than at the start of the test. The ferritic assembly after 4300 cycles showed a corresponding shortening of 0.86 in.

It appears that shifting of the zero point was caused by yielding which tended to alter the form of the loop somewhat. At the conclusion of the test the maximum stress in the austenitic mock-up was 18,000 psi and the minimum stress 8000 psi, as compared to an initial range of 21,900 to 11,200 psi. For the ferritic mock-up, the maximum stress was 10,600 psi and the minimum stress 5500, as compared to the range 15,750 to 9750 psi at the start of the test. Inasmuch as the tests were conducted at constant deflection, the value of the variable stress would not be expected to change materially.

EXAMINATION OF THERMAL-SHOCK ASSEMBLIES AND MOCK-UP FOLLOWING TESTS

The necessity for removing the valves and connecting pipe intact from the thermal-shock specimens for rewelding in the mock-ups has precluded destructive examination of any of the welds excepting those at the ends of the assemblies. In Fig. 1 the various welds of the assemblies are numbered for convenience of reference.

Thermal-Shock Assemblies—160 Schedule. All welds contained in the 160-schedule thermal-shock assemblies were examined by an oil-powder method of flaw detection prior to the thermal-shock test. Also, transition weld No. 6 was macroetched and examined at low power for cracks. Following the thermal-shock test the welds again were examined by the oil-powder method. Those welds showing indications of defects were macroetched and examined. In addition, welds, 5, 6, and 9 were x-rayed, and welds 2 and 9 subjected to a peel test which consisted of removing the weld metal from the groove in increments ranging from 0.0075 to 0.030 in. until no indications of cracks were revealed by oil-powder inspection.

Prior to the thermal-shock test, no cracks were observed in the weldments of the 160-schedule assemblies as a result of oil-powder and macroexamination methods of inspection. Following the thermal-shock test, the oil-powder technique revealed cracks which were not evident prior to the shock treatment. The distribution of these cracks was toward the bottom of the assemblies.

The welds joining austenitic-ferritic pipe, namely, 25-20 in

V-type joints and 19-9 Cb in transition-type joints, showed the greatest tendency to develop cracks. The etched surfaces of the transition joints indicated variations as regards the deposition technique employed, in that, in some portions of the joints the weld metal was deposited stringerwise while in others in oscillations or weaves up to 1 in. in width.

The 19-9 Cb weld metal in the austenitic piping revealed the least tendency toward fissuring. Others⁵ have observed that chromium-nickel compositions of this type, which promote the formation of ferrite, are more resistant to fissuring than are the fully austenitic weld metals. Results of the peel test performed for welds Nos. 2 and 9 showed that cracks indicated on the surface were removed completely after machining to a depth of 0.023 in. for weld No. 2 (19-9 Cb), but persisted to a depth of 0.375 in. for weld No. 9 (25-20).

The welds of the 160-schedule ferritic assembly also revealed cracks following the thermal-shock test, but the number of cracks was less than in the austenitic assembly. The majority of cracks occurred in welds Nos. 10 and 15.

Thermal-Shock Assemblies—80 Schedule. The welds of the 80-schedule assemblies were examined after the manner described for the 160-schedule assemblies. No cracks were observed prior to thermal-shock treatment. Following the thermal-shock tests, cracks were revealed by the oil-powder method but were less numerous and more uniformly distributed than in the 160-schedule specimens. Of the two 80-schedule specimens, the austenitic assembly showed the greater tendency toward fissuring, the number of fissures being much greater in the 25-20 weld No. 2 which happened to be located near the inlet end of the assembly.

The welding technique employed in producing the 25-20 welds in the 80-schedule assembly was at variance with that for similar welds in the 160-schedule assembly in that deposition was stringerwise.

Austenitic Mock-Up—160 Schedule. Further examination of the welds following 4100 deflection cycles of the 160-schedule austenitic mock-up showed an increase in the number and magnitude of cracks in the 25-20 V-joint welds 7 and 8, and in the transition welds 5 and 6. In the case of joint 5, the concentration of defects was apparently on the ferritic side of the joint along the line of fusion between the layer of 25-20 weld metal and the main body of the 19-9 Cb weld metal.

Testing of the 160-schedule ferritic mock-up was not completed in time to include results of oil-powder inspection in the paper.

The fact that cracks or fissures were not revealed in the welds by the oil-powder method until after the thermal-shock treatment might indicate that the defects were potentially present as planes

* .1% set

of weakness from the beginning, and that the stress conditions imposed by the test caused development into fine cracks. If this is correct, it would be expected that continued stressing would further aggravate the defects as has been mentioned for the 25-20 V-joints, welds 7 and 8, and transition welds 5 and 6 of the 160-schedule austenitic assembly. These welds were subjected to both thermal shock and deflection cycles. On the other hand, fissures would not be expected to develop in sound austenitic weldments as a result of the thermal stresses imposed.

Careful and painstaking control of the entire welding process is necessary to avoid fissuring in welds of heavy sections. Opinion differs as to the relative importance of the various factors. The effect of certain residual elements for increasing the susceptibility to cracking in a number of the chromium-nickel weld metals was pointed out by R. D. Thomas, Jr.⁶ The same author observes that cracks may arise from changes in composition of the weld metal by dilution from a dissimilar base metal. O. R. Carpenter and N. C. Jessen⁷ present data to the specifying of core-wire analysis which will produce a minimum of microdefects in deposited 25-20 welds. Anton L. Schaeffler⁸ has presented

a graphical method for predicting weld-metal composition and structure in dissimilar welds. Slight deviations from the applicable technique such as a slower rate of progression, a wider weave, higher preheat, or a higher current have been mentioned by others as contributing factors to the development of fissures in austenitic welds.

LABORATORY TEST PROGRAM

The chemical composition and tensile properties at normal temperature and 1100 F for the test materials are given in Table 3. The tensile properties were determined with standard 0.505-in-diam specimens, most of the results being the average of two or more determinations.

Tensile test results obtained for 0.505-in-diam specimens taken across V-type welds in 6-in. 160-schedule austenitic assemblies are given in Table 4.

Stress-rupture test results at 1000 and 1100 F temperatures for specimens prepared from the austenitic and ferritic pipe materials and cast cylinders are presented in Fig. 12. Similar results for all-weld-metal specimens and specimens taken across V-type welds are shown in Fig. 13. The cast cylinders for simulating valve bodies were 12 $\frac{1}{2}$ -in. long with the bore tapering from mid-point, the maximum wall thickness of 1 $\frac{1}{16}$ -in. being at mid-point.

Fatigue tests were made at 1100 F temperature of conically tapered rotating cantilever specimens prepared from the 160-schedule pipes, the austenitic all-weld metals, and of specimens

taken across V-type welds. The weld zone of the latter was located in the middle of the test length of the specimen, the critical diameter of the tapered test section being 0.357 in. Results of test plotted on a semilogarithmic scale are presented in Fig. 14.

SUMMARY

Thermal-shock tests have been conducted of 6-in. pipe-and-valve assemblies representing both type 347 and 2 1/4 Cr-1 Mo steels in 80 and 160 schedules. The nominal pipe-wall thickness for 80-schedule pipe is 0.432 in. and for 160-schedule pipe, 0.718 in. Each assembly contained two valves, one cast and the other forged, of similar composition to the pipe material. The 160-schedule thermal-shock specimens contained a 36-in. length of dissimilar pipe at mid-length, the type 347 austenitic assembly being provided with a length of 2 1/4 Cr-1 Mo steel pipe, and the ferritic assembly with a length of type 347 pipe. The joints of

the austenitic assemblies were of two kinds, namely, 19-9 Cb and 25-20 chromium-nickel. Transition-type welds were employed between the dissimilar materials in the austenitic assembly. A V-type joint made with 25-20 electrodes was employed between the dissimilar materials in the ferritic assembly. Dissimilar pipe sections were not contained in the 80-schedule assemblies.

The thermal-shock tests were designed to simulate the effect of carry-over of boiler feedwater into main steam lines operating at 900 or 2000 psi pressure, 1050 F temperature. The assemblies were shocked by introducing either 60 or 88 lb of boiler water at the saturation temperature along with the flow of superheated steam. Each assembly was subjected to 100, or more shocks. Temperature differentials in the pipe walls showed that the maximum temperature difference between the inside and outside of the wall was obtained for the ferritic-steel assemblies. Moreover, the maximum temperature difference occurred in a much

shorter time in the case of the ferritic steel. All four thermal-shock specimens withstood 100 or more shocks without failure by rupture.

Measurements of the assemblies following the tests showed that the ends of the 160-schedule assemblies had been distorted upwardly about 0.10 in. at the inlet end and 0.20 in. to 0.25 in. at the outlet end. The rate of decrease in fracture stress with time at 1100 F temperature, as shown in Fig. 13, for specimens taken across welds joining a section of austenitic-steel pipe and an austenitic-steel casting was disconcerting. However, similar tests of specimens taken across welds joining two sections of austenitic-steel pipe have indicated normal behavior in this respect.

Fatigue tests at 1100 F temperature have shown considerable superiority for the 18-8 Cb pipe material. The fatigue strength for the 19-9 Cb all-weld metal is considerably lower than for the pipe material and apparently controls the fatigue strength of specimens taken across 19-9 Cb welds joining sections of pipe. Similar specimens taken across welds joining 18-8 Cb pipe to austenitic castings showed lower fatigue strength. Comparable fatigue values between 10^7 and 10^8 cycles are indicated for 25-20 weld metal and $2\frac{1}{4}$ Cr-1 Mo pipe material at 1100 F temperature.

ACKNOWLEDGMENTS

The guidance and assistance received from the Special Subcommittee under the chairmanship of Mr. N. L. Mochel throughout the course of this investigation is gratefully acknowledged. The authors also wish to express their appreciation to Capt. W. D. Leggett, Jr., U.S.N., Director of the Naval Engineering Experiment Station, and Capt. C. G. Grimes, U.S.N., Assistant Director of Laboratories, for their encouragement and support.

Discussion

M. L. IRELAND, JR.* The marine and stationary power-plant industries are both fortunate to have available the important results presented in this paper.

It is reassuring that the piping materials withstood tests of such severity with only the small amount of damage indicated. Presumably these tests correspond to the expected number of thermal shocks and normal heating and cooling cycles which will be received by similar pipe in a service life of 20 years.

Such tests are of too-short duration to give much indication of the effect of long-time exposure under sustained pressure stresses. It has been suggested that the reported cracks in the welding zone are due to enlargement of microfissures which may have been present before the test.

If this explanation is accepted then does it not appear likely that further enlargement will occur during long-time exposure at the service temperature, even if the only stresses present are those due to internal pressure?

In view of this fact, it would appear desirable to perform stress-rupture or creep tests on specimens cut from the affected areas but at moderate stress levels, corresponding to the operating conditions.

Since this program was initiated, a rational method for calculating temperature gradients in a pipe subjected to thermal shock has become available.¹⁰ However, this method requires use of a constant value for the internal surface heat-transfer coefficient. A value of 1000 Btu/hr ft² F was used in these calculations since it was expected that surface evaporation would occur.

FIG. 14 ROTATING CANTILEVER FATIGUE-TEST; TESTING TEMPERATURE 1100 F

The following illustrations show how the calculated temperatures compare with the test values reported in the paper. Fig. 15 is for the ferritic schedule-160 piping and shows quite good agreement except for thermocouples T-3 and T-4.

The initial difference shown for thermocouple T-4 before start of the quench indicates that this element was subject to some error. It is possible that this was caused by heat losses due to partial exposure.

Another possibility is that wet superex insulation may have been applied over this element and the insulation insufficiently dried out before testing. The writer has recently employed thermocouples peened on the outside of a pipe to measure steam temperatures and found an error of the same order (25 F) which persisted throughout an entire one-day sea trial. Laboratory tests showed that about 24 hr at temperature were required to dry out the insulation sufficiently to give accurate readings.

Fig. 16 is a similar comparison of test and calculated values for the ferritic schedule-80 piping and shows about the same numerical difference but in the opposite direction.

The test temperatures near the outer wall are higher than the calculated values for schedule-160 pipe, but lower than calculated values for schedule-80 pipe.

Comparisons for the two thicknesses of austenitic piping are shown in Figs. 17 and 18. In both these cases the observed temperature differences across the pipe are very much less than calculated, and the discrepancy is too great to be ascribed to errors in temperature measurement.

In order to explain this discrepancy the indicated surface heat-transfer rates were computed from the test data by summing up the pipe-wall temperature changes for any interval of time. The surface temperature gradient was assumed to be the difference between thermocouple T-1 and the saturation temperature. The log-mean temperature difference was used for the initial phase when the inner pipe-wall temperature was changing rapidly. The results of these calculations are shown in Fig. 19.

These results are considerably different from the assumed surface heat-transfer coefficient of 1000, and, in general, account for the differences between observed and calculated temperatures in the pipe wall.

However, the differences in test heat-transfer coefficients still remain to be accounted for. It appears reasonable to expect some delay in establishing the full value of this coefficient, but it is difficult to understand why the 18-8 piping should have a much slower response and reach lower final values. The rapid drop in value for the schedule-80 ferritic piping is also curious.

FIG. 15 THERMAL GRADIENTS FOR SCHEDULE-160 $2\frac{1}{4}$ CR-1 MO PIPE. COMPARISON OF CALCULATED VALUES WITH TEST RESULTS

It would be helpful to know just how consistent the thermocouple readings were between successive quenches of the same piping assembly, as this would indicate what variation is to be expected in the heat-transfer curves in Fig. 19.

One further item which should be established is the actual pipe-wall thickness at the points of temperature measurement. It is assumed that the piping was ordered to minimum wall specifications, in which case there is a permissible overthickness tolerance of 22 per cent.

It is hoped that this discussion has suggested some further lines of inquiry which ultimately will add to the value of the test results.

V. T. MALCOLM¹¹ AND SIDNEY LOW.¹² For many years it has been the hope of both the power-plant and refinery design engineers that they would have a sufficient amount of information with regard to this elusive condition. Due to the lack of knowledge of the conditions existing in high-temperature steam lines, flange joints were gradually abolished and replaced with welded joints.

The selection of materials for service at elevated temperatures above 900 F is a complex problem and usually results in a compromise of a number of important design and fabricating features, such as the following:

¹¹ Director of Research, The Chapman Valve Manufacturing Company, Indian Orchard, Mass.

¹² Research Engineer, The Chapman Valve Manufacturing Company. Jun. ASME.

FIG. 16 THERMAL GRADIENTS FOR SCHEDULE-80 $2\frac{1}{4}$ CR-1 MO PIPE. COMPARISON OF CALCULATED VALUES WITH TEST RESULTS

- 1 Strength and ductility at operating temperatures.
- 2 Resistance to oxidation and scaling.
- 3 Resistance to corrosive attack.
- 4 Retention of satisfactory mechanical and other properties after extended exposure under operating conditions.
- 5 Resistance to thermal stresses in applications involving intermittent heating and cooling which eventually may cause deformation or cracking.
- 6 Weldability of the materials.
- 7 Structural stability.
- 8 Ease of fabrication.
- 9 Cost.

Adequacy of a given design, from a structural standpoint, requires that it be strong enough under the anticipated service conditions and that the stress imposed at the operating load and temperature be less than the strength of the material for long periods. At the same time, the imposed stress should not be much less than the strength of the material at temperature, if the design is to be practicable. Therefore all factors must be considered individually, especially such factors as consequence of failure, economic production, and degree of performance and life desired.

In the introduction we find that the authors were prompted to use the 18-8 chromium-nickel steel for 1050 F service due to the fact that it had superior high-temperature properties over the ferritic types of steel and would permit the use of thinner and lighter pipe at higher pressures. This is common practice among many design engineers who have based their designs on weight saving due to better stress values, but this thinking is

FIG. 17 THERMAL GRADIENTS FOR 160-SCHEDULE 18 CR-8 NI PIPE. COMPARISON OF CALCULATED VALUES WITH TEST RESULTS

FIG. 19 HEAT-TRANSFER COEFFICIENTS DURING THERMAL-SHOCK TESTS

likely to be misleading because most of the allowable working stresses are obtained from 80 per cent of the 1 per cent creep in 100,000 hr. However, in the analysis of steels; that is, ferritic and austenitic steels, we would very likely find that at certain stress levels within indicated temperature range, the austenitic steels may be deforming at a much more rapid rate than the ferritic steels. This condition is a well-known fact in refinery work where severe oversteering may be encountered.

In 1933¹³ and in 1938,¹⁴ considerable information was given on the behavior of austenitic and ferritic steels at temperatures from 900 to 1100 F, and service hours up to 48,361 of which 38,921 had been at 1100 F. Examination of the 18-8 chromium-nickel austenitic steel showed that the material deteriorated in service due, probably, to the precipitation of chromium carbides along the grain boundaries. No stabilizing elements were present in the austenitic steel. There was no evidence of any serious reduction in physical properties when operating in steam service in the 1000-1100 F range.

It was also reported that tests of other steels of the low-alloy class disclosed no marked change in their properties in this service. Certain tubing and castings were made of a low-alloy, 4-6 per cent chromium with 1 per cent tungsten. It was reported, after a total service of nearly 11,000 hr at 1100 F, that the material did not undergo embrittlement, and that long service at high temperatures tended to increase toughness and ductility. It was also reported that "austenitic steel was growing at the average rate of 4.4 per cent per 100,000 hr, while alloy tubes were growing at a corresponding rate of 5.3 per cent. However, measurements of a 4-6 per cent chromium-tungsten tube after service of 7465 hr showed no change in dimensions." No evidence of thermal shock was reported.

The authors call attention to the fact that experience has been cited which indicates strength deficiencies for austenitic-steel castings as well as for welded joints between austenitic pipe and castings. It is a well-known fact at the present time that if the composition of austenitic steel is carefully controlled, with respect to the chromium and nickel equivalents, strength will not be lacking. This same composition balance applies to welded joints.

The writers agree there is a great difference between the use of austenitic steels in the refinery and in the power plant and also agree with the mechanism as brought out by the authors, but believe that mechanical stresses have very little to do with any damage that may be incurred, and that it is clearly one of thermal stress. However, the great question is how are we to measure these thermal stresses when they occur so rapidly and are transient in effect rather than a steady change of temperature?

One of the mistakes made by many people is that they consider the austenitic steels of 18-8 to be single-phase alloys. This is not true because we know that austenite is not thermodynamically stable at room temperature, with the result that we are likely to have a two-phase alloy, in which one portion is ferrite, while the other is undergoing transformation from austenite.

In the stress calculations the authors have assumed that the temperature varied linearly between successive readings, as shown by Timoshenko's thermoelastic formula.¹⁵ This assumption, however, may not be correct particularly in medium-heavy walls, as denoted by a valve where the stationary temperature distri-

bution is no longer a linear function of r and is represented by Equation [239].¹⁶

The tendency of the two types of austenitic weld deposits presumably to fissure during stress cycling is quite disturbing in view of the large number of similar austenitic welds currently employed in various types of piping construction.

Although if the 19-9 Cb weld metal has a calculated ferrite content of 10 per cent, coupled with a low C: Si ratio and a low P content, it is not improbable that the deposit was fissured prior to test. It has been our experience that penetrant-oil inspection of weld deposits is only 100 per cent sure if the deposit has been finely machined or ground. The oil method of inspection is particularly unsatisfactory when the weld deposit is ground manually or rough-machined. Peening of the weld deposits also has the effect of closing any fissures present and rendering the oil-inspection method ineffectual. These same remarks also apply to 25-20 weld deposits which, of course, are even more susceptible to fissuring in the as-deposited condition. The inclusion of bend-test results of both the 19-9 Cb and 25-20 welds might define more conclusively the quality of the welds.

It has always been our opinion that fissuring is essentially a high-temperature phenomenon, taking place appreciably above the maximum temperature encountered in steam service. The mechanism of fissuring is essentially the same as the mechanism of hot-tearing encountered in castings. In many cases, the formation and the propagation of these fissures may be observed during the actual welding operation, as the deposit solidifies behind the arc. This is particularly true of alloys of the 10 Cr-20 Ni type and certain high-nickel corrosion- and/or heat-resistant alloys.

If it is true that both the 19-9 Cb and the 25-20 weld deposits were fissure-free as deposited, the fact that fissures formed below 1100 F during thermal cycling is quite disconcerting. However, if macro- (or micro-) fissures were present prior to thermal cycling, it is not surprising that they would grow in width and length sufficiently to permit their detection by oil inspection (in view of the relatively high notch sensitivity of these materials).

Since the authors observed that fissuring was more severe in the 25-20 weld than in the 19-9 Cb weld, would it not be logical to presume that a 20-8 Cb deposit would have less (or perhaps no) fissures?

The presence of cracks in the welds of the 160-schedule ferritic assembly is somewhat more disconcerting than those observed in the austenitic assemblies.

Since the authors use the term fissures with respect to the austenitic welds, and cracks with respect to ferritic welds, it is presumed that their physical appearance differed, and the temperature at which they formed differed.

It is noted that a minimum preheat temperature of 400 F was maintained during welding; this relatively low preheat, coupled with a low rate of heat input during the deposition of the first pass, conceivably could result in a low ductility-transformation product susceptible to cracking. There have also been reports of root cracking using the 10-deg taper ring in a poorly "fitted-up" joint. Do the authors conclude that the cracks observed were in any way related to the welding practice, or to the "ingotism" of the initial passes?

On the basis of the S-N curves shown in Fig. 14 of the paper, and the stress calculations made by the authors, it appears that the various assemblies could be cycled 100,000 times without any fear of actual failure of the welds. Do the authors feel that it is safe engineering to extrapolate their cycling test results on the basis of the S-N curves?

C. T. EVANS.¹⁷ Were the welds cracked before the tests were started, the cracks not being detectable by conventional methods of inspection?

Were the tests abnormally severe?

AUTHORS' CLOSURE

Mr. Ireland's thorough analysis of our results is greatly appreciated. It is certainly true that it would be desirable to perform stress rupture and creep tests on samples cut from the test members and particularly from areas which show small cracks. It is planned to do this when it is decided that no further tests on the complete assemblies will be carried out.

The method for predicting unsteady-state temperatures in a cylindrical shell as referred to in the discussion is based on the assumption that the pipe wall is a flat plate. Other approximate methods are of course, available, such as the graphical or numerical method employing finite increments, and the electrical analog, and these can employ a variable coefficient of heat transfer. In so far as is known here the mathematical method based on a constant heat-transfer coefficient has not yet been applied to this case. In view of the uncertainty of necessary assumption, it would seem that the agreement between the test and calculated results indicated in Figs. 15 and 16 of the paper, is quite satisfactory. It must be remembered that these are in the nature of operating tests, rather than research experiments conducted under rigidly uniform conditions. While the test assemblies were uniform in arrangement it is possible that the flow of quench water, fairly reproducible in any one setup, was not exactly the same in all four. This might possibly account for the surface transfer coefficients being lower at the thermocouple positions in the case of the austenitic samples. It is also possible that the austenitic alloy surface has by nature a lower heat-transfer coefficient for the boiling of water.¹⁸ Figs. 17, 18, and 19 of the paper, can be interpreted, in general, by either of these explanations. In fact, if the latter be correct, the ferritic alloy in these tests is actually being shocked more severely than the austenitic alloy.

The initial temperature drop from T-1 to T-4 can be shown to be approximately what would be expected under the conditions of insulation at the location of the thermocouples, namely, radiation from the hot pipe to the room, with one intermediate baffle of larger size. Thus, it is believed that any errors in the thermocouples are considerably smaller than the temperature differences from T-1 to T-4.

The general shape of the time-temperature curves for the several thermocouples were in good agreement. The maximum temperature differentials for a number of quenches made on the 160 schedule austenitic assembly follow:

Average maximum temperature difference between T-1 and T-4 thermocouples for 27 quenches with 60 lb of water when couples T-1 and T-4 were recorded simultaneously—180 F.

Standard deviation—12.6 F.

Average maximum temperature difference between T-1 and T-4 thermocouples for 6 quenches with 88 lb of water when couples T-1 and T-4 were recorded simultaneously—179 F.

Standard deviation—10.8 F.

As shown in Fig. 3 of the paper, the thermocouples are held in wells in the pipe wall by means of coil springs. An opening about 3 in. square was left in the insulation to accommodate the spring assembly. Although this opening was a relatively dead air space, it would account for some heat loss. The writer's precaution against the use of wet insulating material is well taken. Actually, the insulation was in dry block form; first 2 in. of diatomaceous

earth, then 2 in. of 85 per cent magnesia, followed by a seal coat. Only the seal coat was put on wet, and, subsequently, this was thoroughly dried.

The pipe wall and depth of the thermocouple wells were measured carefully prior to welding.

The authors wish to thank Messrs. Malcolm and Low for their informative discussion of the paper.

The question was raised as to whether austenitic steels might not deform at a more rapid rate than ferritic steels at certain stress levels within the indicated temperature range. At certain stress levels and temperatures, transition from second-stage to very active third-stage creep may occur in austenitic steels even after thousands of hours at a fairly constant creep rate. Hence, the importance of knowing the time of transition between second- and third-stage creep. Yield-strength values at 0.2 per cent offset for the austenitic cast steel at room temperature and 1100 F, as shown in Table 3 of the paper, are lower than for the other materials. Consequently, highly stressed components of austenitic cast steel would be more likely to deform, and this observation is supported by experience. For this reason, and because of inferior high-temperature strength of welds adjacent to castings, the use of austenitic steel castings is not contemplated for main steam lines. The thermal-shock tests produced less distortion in the austenitic test assemblies than in the ferritic assemblies. However, the assemblies were of welded construction and contained no austenitic cast-steel flanges. Maximum distortion occurred in the 80 schedule ferritic assembly.

Stabilized types of austenitic chromium-nickel steel in lieu of similar types containing no stabilizing elements are indicated for the service temperatures mentioned by Messrs. Malcolm and Low. The steel they refer to as showing deterioration after a long time at temperature below 1000 F contained no stabilizing elements.

It is realized that the austenitic steels of the 18-8 type are not necessarily single-phase alloys. In fact a reference cited in the paper observed that chromium-nickel compositions which promote the formation of ferrite are more resistant to fissuring than are fully austenitic weld deposits.

At the outset of the investigation it was considered that thermal stresses might be more important than mechanical stresses when considering austenitic steel for steam piping for high-pressure, high-temperature service. It was with this in mind that the thermal-shock assemblies were fabricated and tested.

In the stress calculations presented in the paper the assumption was made that the temperature varied linearly between successive readings. While this method is not strictly valid, it was considered sufficiently accurate for the purpose.

Messrs. Malcolm and Low remark that the tendency for the two types of austenitic weld deposits to presumably fissure during stress cycling is quite disturbing in view of the large number of similar austenitic welds currently employed in various types of piping construction.

This situation is disturbing to the authors as well. The presence of fissures in the welds indicates a serious need for improved welding procedures and guidance for the welding of high-pressure, high-temperature steam piping. This need would not appear so conspicuous if the defects had been found only in the austenitic welds, for after all, the austenitic material was the subject of experiment. The development of similar defects in the ferritic welds is cause for serious consideration. This material was included in the test for comparison purposes and its suitability for the proposed service was not questioned. It is believed that sufficient technical information is available to insure sound conventional type welds in these materials provided painstaking control of the entire process is exercised.

Although oil powder and zygo methods of inspection failed to

¹⁷ Chief Metallurgist, Elliott, Company, Jeannette, Pa.

¹⁸ "Heat Transmission," by W. H. McAdams, second edition, McGraw-Hill Book Company, Inc., New York, N. Y., 1933, pp. 300-304.

reveal fissures before the tests, the defects were probably present in an incipient stage. The 19-9 weld deposits showed much less tendency toward fissuring than did the 25-20 weld deposits. It does not seem unlikely that fissures might be disclosed in austenitic welds in service if the surfaces are smoothly finished and carefully examined.

The authors did not intentionally use the term fissure with respect to the austenitic welds and crack with respect to the ferritic welds. The two terms indicate the same type of defect, that is, parting of the metal or a tear.

Root cracks observed in the welds are associated with lack of fusion at the root which points to undesirable features in the joint design. Subsequent experiments have indicated the desirability of increasing the root opening from $1/8$ in. to $3/8$ in. and employing a flat, split backing ring in lieu of the backing ring shown in Fig. 2 of the paper. It is also indicated that deposition should be

stringerwise, the thickness of each stringer not to exceed $1/8$ in.

The authors would not advise extrapolating the cycling test results for the full-scale assemblies on the basis of S-N curves obtained for laboratory test specimens. However, they do consider it advisable to continue the testing of the mock-ups at higher stress levels until failures are produced.

In answer to Mr. Evan's questions:

The oil powder and zygo methods of inspection failed to reveal the surface defects before the tests were started.

The thermal-shock test of 100 cycles might be considered rather severe but not necessarily more severe than might occur during the service life of a piping system. The 4000 deflection cycles imposed on the mock-ups represent stress conditions produced on heating up a piping system every other day for approximately 20 years, the maximum allowable stress being 25 per cent greater than that permitted by the ASME Boiler Code.

Optimum Tube Size for Shell-and-Tube-Type Heat Exchangers

By F. D. CARDWELL,¹ NEW YORK, N. Y.

The total annual cost for a shell-and-tube-type heat exchanger, which is the sum of the annual power cost plus the fixed charges or annual amortization of the initial cost of the equipment, is found to vary sharply with small changes in tube size when the heat-transfer rate is held constant. Equations are developed reducing the number of assumptions to length of tubes and diameter of tubes for fixed design conditions such as total flow rates in shell and tube and required heat-transfer rate. For a selected length as a parameter, then, the total annual cost can be calculated for each tube diameter. The optimum tube diameter is determined from a graph of these corresponding values which has a well-defined minimum value for the total annual cost. A family of these curves, each having a different length as the parameter, will each have a minimum. These minimal values will all be nearly equal. Another family of curves with standard tube diameter as the parameter will each have a minimum giving the optimum length for each diameter. Therefore only one convenient parameter need be selected from which the optimum combination can be determined from a curve. Since the required heat-transfer-surface area is now known, the number of tubes for this combination follows automatically.

NOMENCLATURE

The following nomenclature is used in the paper:

- A = area, sq ft
- A_e = area available for flow in each tube, sq ft (see Fig. 2, and text)
- A_i = surface area for heat transfer based on inside diameter of tube, sq ft
- A_o = surface area for heat transfer based on outside diameter of tube, sq ft
- A_s = total sectional area available for flow in shell outside of and parallel to tubes, sq ft
- C = constant based on fixed design conditions and defined in text
- C_{pt} = specific heat of fluid in tubes, Btu/(lb) (deg F)
- C_{ps} = specific heat of the fluid in shell, Btu/(lb) (deg F)
- D_o = diameter of circle having an area equal to area A_e , ft
- D_i = inside diameter of tube, ft
- D_o = outside diameter of tube, ft
- D_e = hydraulic diameter, ft
- D_s = inside diameter of shell, ft
- f = friction factor, function of Reynolds number, and used in Fanning formula, see text Equation [34]
- G_i = mass flow of fluid in tubes, lb/(hr)(sq ft)

- G_o = mass flow of fluid in shell, parallel to tubes, lb/(hr)(sq ft)
- g = acceleration due to gravity, 32.16 ft/sec²
- h_i = film coefficient of fluid film on inside tube wall based on mean bulk temperature of fluid, Btu/(hr) (sq ft) (deg F)
- h_o = film coefficient of fluid film on outside tube wall based on mean bulk temperature of fluid, Btu/(hr) (sq ft) (deg F)
- L = length of tube, ft
- N = number of tubes
- P = equiangular tube spacing, ft
- ΔP_i = total pressure drop for fluid inside tubes, psf
- Q = total heat required to be transferred, Btu per hr
- R = ratio of tube spacing to outside tube diameter, P/D_o
- Re = Reynolds number
- S = total annual cost, fixed charges plus operating cost, dollars
- Δt_{LM} = log-mean temperature difference, corrected for multipass
- U = over-all coefficient of heat transfer, Btu/(hr) (sq ft) (deg F)
- V = velocity of fluid in tubes, fps
- W_i = total flow of fluid in tubes, lb per hr
- W_o = total flow of fluid in shell, lb per hr
- WP = wetted perimeter, ft, used in calculating hydraulic diameter
- α = constant based on design conditions, defined in text
- β = constant based on design conditions, defined in text
- γ = constant based on design conditions, defined in text
- θ = constant based on design conditions, defined in text
- μ_i = viscosity of fluid in tubes, lb/(hr) (ft)
- μ_o = viscosity of fluid in shell, lb/(hr) (ft)
- ρ_i = density of fluid in tubes, lb per cu ft
- ρ_o = density of fluid in shell, lb per cu ft

INTRODUCTION

Heat-exchanger calculations are based upon (a) design conditions, i.e., fluid-flow rates, terminal temperatures, thermal properties of the fluids and allowable pressure drop; (b) assumptions, i.e., heat-transfer-surface area, over-all coefficient of heat transfer, or size, length, or number of tubes; (c) pressure drop across the exchanger. The design conditions are fixed by over-all plant design and determine the expected performance of the exchanger. The assumptions are more or less arbitrary with the engineer and are based upon his personal experience. Trial-and-error calculations of film coefficients are used to check the assumptions, which are also checked by an over-all heat balance. Finally, the pressure drop is calculated and compared with the allowable. If the calculated drop is too high, a new set of assumptions is made and rechecked as before.

A set of assumptions which check out and satisfy the design conditions may not be the optimum set when fixed charges and power costs are considered. Annual fixed charges is that part of the initial cost which is written off each year on the books of the owner. The actual amount written off then depends upon initial cost and company policy. In turn the initial cost depends upon

¹ Research Engineer, Chemical Construction Corporation. Mem. ASME.

Contributed by the Heat Transfer Division and presented at the Spring Meeting, Washington, D. C., April 12-14, 1950, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Manuscript received at ASME Headquarters, December 6, 1949. Paper No. 50-8-G.

the heat-transfer-surface area and the prevailing price of steel. Analytically, then, fixed charges are primarily a function of the surface area, which includes the prevailing market price, and the accounting policy of the owner. The annual power cost depends upon pressure drop and local electric-power rates where motor-driven blowers are used, or fuel rates where steam-driven blowers are used. The total annual cost is the fixed charges plus the power cost. The optimum design, then, is the one that will result in the lowest total annual cost, and still deliver the required heat-transfer rate.

It is easily seen that a great amount of labor would be involved if one attempted to determine the optimum design by using the method of assumptions and trial-and-error calculations as outlined. Fortunately, a method of direct calculation has been found whereby the optimum design can be determined definitely in about the same time as before. Furthermore, there has been found to be not only one optimum design but several; for instance, if, say, the length of tube is chosen, an optimum design can be quickly determined for that particular length, while if some other length of tube is decided upon, the optimum design can be found for that length, and so forth, and when these optimums are compared the difference in total annual cost is negligible. Therefore the method is quite flexible in that the length of tubes is arbitrary and can be chosen independently. This is a great convenience since available space may be a factor in the design which would limit the length of the tubes. On the other hand, the size of tube may be chosen and the optimum design determined for that particular tube diameter. The development of this method follows.

HEAT TRANSFER

If we write the Newton formula

$$Q = UA \Delta t_{LM} \quad [1]$$

in the form

$$\frac{Q}{\Delta t_{LM}} = UA \quad [2]$$

we have on the left-hand side of Equation [2] the design conditions, and on the right-hand side, a product of two variables whose respective values depend upon both design conditions and the usual assumptions. These two factors must satisfy the equations for film coefficients as well as Equation [2].

Let us consider a simple gas-to-gas shell-and-tube-type heat exchanger with turbulent flow. The arrangement includes fixed tube sheets with two baffles as shown in Fig. 1. Also, to make the development as simple as possible, we will neglect the tube-wall resistance and fouling factors. The following development can be worked out for more complicated arrangements but this will not be attempted in the present paper.

Using the well-known resistance concept, we can write for the elemental areas dA_i and dA_o .

$$\frac{1}{UdA} = \frac{1}{h_i dA_i} + \frac{1}{h_o dA_o} \quad [3]$$

The elemental areas may both be expressed in terms of the elemental length dL , as follows

$$dA_i = \pi N D_i dL \quad [4]$$

and

$$dA_o = \pi N D_o dL \quad [5]$$

Substitution of Equations [4] and [5] in [3] gives upon solving for UdA

$$UdA = \frac{\pi N h_i D_i dL}{1 + \frac{h_i D_i}{h_o D_o}} \quad [6]$$

Actually, the values of the film coefficients and the overall coefficient will vary along the length of the tube because the bulk temperature of the fluids varies with the length. This will result in the variation of the conductivities and viscosities of the fluids upon which values the local coefficient will depend. However, it is reasonably safe for all practical purposes to use values of film coefficients based on the mean bulk temperatures of the fluids.

Integration of Equation [6] then gives

$$UA = \frac{\pi N h_i D_i L}{1 + \frac{h_i D_i}{h_o D_o}} \quad [7]$$

Using a mean value of 0.78 for the Prandtl number, the formula for the tube-side film coefficient as given by McAdams is

$$h_i = \frac{0.027 C_{pi} G_i^{0.8} \mu_i^{0.2}}{D_i^{0.2}} \quad [8]$$

The mass flow in the tubes, G_i , is

$$G_i = \frac{4W_i}{\pi D_i^2 N} \quad [9]$$

and substitution of Equation [9] in [8] gives

$$h_i = \frac{\alpha}{N^{0.5} D_i^{1.5}} \quad [10]$$

where

$$\alpha = 0.0327 C_{pi} \mu_i^{0.2} W_i^{0.8} \quad [11]$$

We have thus further simplified the formula for the tube-side film coefficient to the point where each factor appears only once. Furthermore, the fixed design conditions, C_{pi} , μ_i , and W_i have been separated from the usual assumptions N and D_i .

While formulas for film coefficients for fluids flowing across tube banks have been developed to a fair degree of correlation,² there is no completely satisfactory formula for the shell-side coefficient for the case of numerous baffles. Therefore the shell-side arrangement has been simplified to the point where the fluid can be considered flowing parallel to the tubes, Fig. 1. The

FIG. 1 TYPICAL SINGLE-PASS COUNTERFLOW, SHELL-AND-TUBE-TYPE HEAT EXCHANGER WITH FIXED TUBE SHEETS

hydraulic diameter is used as in annular spaces² and is determined as follows:

² "Heat Transmission," by W. H. McAdams, second edition, McGraw-Hill Book Company, Inc., New York, N. Y., 1942.

A typical is made, using tube sheet is excessive radii number of tubes. The graph of D_o/P and D_i is the line will result is

and substit simplified fo

² Standard

A typical tube-sheet layout with tubes on triangular centers is made, using the minimum spacing 1.25 tube diameters.³ The tube sheet is divided by a series of concentric circles, whose successive radii are 1, 2, 3, etc., tube spacings. The maximum number of tubes (N) in each circle is then counted. Now if a graph of D_s/P versus \sqrt{N} is made, where P is the tube spacing and D_s is the diameter of the circle containing N tubes, a straight line will result whose slope is found to be 1.09. The formula then is

$$\frac{D_s}{P} = 1.09\sqrt{N} \quad [12]$$

Equation [12] is a good approximate relationship and will hold for tube spacings up to 1.5 tube diameters. Also, since the ratio D_s/P is dimensionless, Equation [12] will hold for all sizes of tubes. The standard deviation for the range, $31 < N < 1135$, is 1.4 per cent.

Writing Equation [12] in the form

$$D_s = 1.09 P \sqrt{N} \quad [13]$$

and by definition

$$P = R D_o \quad [14]$$

Substitution of Equation [14] in [13] gives

$$D_s = 1.09 R D_o \sqrt{N} \quad [15]$$

The sectional area available for flow parallel to the tubes is from the geometry of the tube sheet

$$A_s = \frac{\pi(D_s^2 - N D_o^2)}{4} \quad [16]$$

and substitution of Equation [15] in [16] gives

$$A_s = \frac{\pi N D_o^2 (1.188 R^2 - 1)}{4} \quad [17]$$

The wetted perimeter will be

$$WP = \pi(N D_o + D_s) \quad [18]$$

and substitution of Equation [15] in [18] gives

$$WP = \pi D_o (N + 1.09 R \sqrt{N}) \quad [19]$$

Now, since the hydraulic diameter is equal to 4 times the sectional area divided by the wetted perimeter, we can write, using Equations [17] and [19] and simplifying

$$D_h = \frac{D_o (1.188 R^2 - 1)}{1 + 1.09 R / \sqrt{N}} \quad [20]$$

The mass flow of the shell-side fluid parallel to the tubes will be the total flow divided by the sectional area

$$G_s = \frac{4 W_o}{\pi N D_o^2 (1.188 R^2 - 1)} \quad [21]$$

The formula for the shell-side film coefficient is, then, using the hydraulic diameter with Equation [8]

$$h_o = \frac{0.027 C_{\rho_o} G_s^{0.8} \mu_o^{0.2}}{D_h^{0.2}} \quad [22]$$

and substitution of Equations [20] and [21] in [22] gives the simplified formula

³ Standards of Tubular Exchanger Manufacturer's Association.

$$h_o = \frac{\beta}{N^{0.5} D_o^{1.5}} \quad [23]$$

where

$$\beta = \frac{(0.026)(1 + 1.09 R / \sqrt{N})^{0.2} C_{\rho_o} \mu_o^{0.2} W_o^{0.8}}{(1.188 R^2 - 1)} \quad [24]$$

For values of N , ranging from 100 to 1000, and values of R , ranging from 1.25 to 1.50, the quantity

$$(1 + 1.09 R / \sqrt{N})^{0.2}$$

has a maximum variation of only 2.22 per cent. Therefore we can safely use the mean value of this quantity, 1.02, in order to simplify Equation [24] obtaining

$$\beta = \frac{0.0263 C_{\rho_o} \mu_o^{0.2} W_o^{0.8}}{1.188 R^2 - 1} \quad [25]$$

At this point Equation [25] can be simplified further by choosing some value for R . Further, for any particular arrangement, an optimum value for R can be found. However, Shepherd⁴ has shown that an optimum value of R is 1.45. This value will be used in our development. Substituting this value in Equation [25] we obtain

$$\beta = 0.0176 C_{\rho_o} \mu_o^{0.2} W_o^{0.8} \quad [26]$$

As a point of interest at this stage, the inside and outside film coefficients can now be compared directly by looking at Equations [26] and [11], since the two Equations [10] and [23] are identical in form. The ratio of these coefficients is found to be, when all other factors are equal

$$h_i/h_o = 1.86 \quad [27]$$

A smaller value of R or the use of baffles would naturally reduce this ratio to a point where the shell-side film coefficient would be as great as or greater than the tube-side film coefficient. However, the use of baffles has its limitations in both original cost and power cost by increasing the pressure drop on the shell side. Then, too, some stagnant areas are caused by baffles which reduce the effective heat-transfer area. The question is still open and will be neglected in this paper.

We can now substitute Equations [10] and [23] in [7] obtaining

$$UA = \frac{\pi \alpha \beta N^{0.5} L}{\beta D_i^{0.5} + \alpha D_o^{0.5}} \quad [28]$$

Equation [28] may be written

$$N^{0.5} = \frac{UA(\beta D_i^{0.5} + \alpha D_o^{0.5})}{\pi \alpha \beta L} \quad [29]$$

and substitution of Equation [2] in [29] gives

$$N^{0.5} = \frac{Q(\beta D_i^{0.5} + \alpha D_o^{0.5})}{\pi \alpha \beta \Delta T_{LM} L} \quad [30]$$

or

$$N = Q^2 \left[\frac{\beta D_i^{0.5} + \alpha D_o^{0.5}}{\pi \alpha \beta \Delta T_{LM} L} \right]^2 \quad [31]$$

The heat-transfer-surface area,⁵ based on the inside tube

⁴ "A Design Method for Counterflow Shell-and-Tube Heat Exchangers for Gas Turbines," by D. G. Shepherd, presented at the Annual Meeting, Atlantic City, N. J., December 1-5, 1947, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

⁵ In the example the inside surface area is controlling. The log-mean surface area could be used but would only complicate the development unnecessarily.

diameter, then becomes from substitution of Equation [31] in $A_i = \pi D_i N L$

$$A_i = \pi D_i C^3 (\beta D_i^{0.8} + \alpha D_o^{0.8})^3 / L^4 \quad [32]$$

where

$$C = \frac{Q}{\pi \alpha \beta \Delta T L M} \quad [33]$$

It will be noted at once that the constant C is a function of the design conditions only and, for a given set of design conditions, this constant will have to be calculated only once. Moreover, it will be noted that the number of tubes N , has been eliminated from the final Equation [32]. This reduces the assumptions to only two, namely, the length and size of tubes. Of course N can always be calculated from Equation [31] for any size and length of tubes chosen, but this is supplemental to our method. The required area can always be determined directly from Equation [32].

Since we have eliminated the assumption (N) from our heat-transfer calculations, our problem now is to eliminate the same assumption from the pressure-drop calculations. There are two separate sets of pressure-drop calculations; one set is for the flow in the tubes, the other set is for the flow in the shell. For the particular design under consideration, the shell-side pressure drop is negligible and will not be considered in this paper.

Where many baffles are used, the shell-side pressure drop is quite large and should not be neglected. However, a satisfactory method of calculation of shell-side coefficients, where numerous baffles are used, has not been developed for general use as of today. As soon as some reliable method is available, the author hopes to extend this development to include pressure-drop and heat-transfer calculations for the shell side using any number of baffles.

PRESSURE DROP

The tube-side pressure drop includes the entrance and exit losses as well as the friction loss in the tubes. For convenience, all losses will be expressed in pounds per square foot. The friction loss in the tubes is found from the well-known Fanning formula

$$F = 4f \left(\frac{L}{D} \right) \left(\frac{V^2}{2g} \right) \quad [34]$$

The entrance and exit tube losses are based on the equivalent diameter ratio which is determined from the unit area in the head for each tube, which is available for flow at the tube entrance or exit. From geometry, Fig. 2, this area is

$$A_s = 0.866 P^2 \quad [35]^6$$

but by definition

$$P = R D_o \quad [36]$$

and substitution of this value in Equation [35] gives

$$A_s = 0.866 R^2 D_o^2 \quad [37]$$

The equivalent diameter corresponding to this area is

$$D_o = \sqrt{1.103 R^2 D_o^2} \quad [38]$$

and the equivalent diameter ratio becomes

$$\frac{D_i}{D_o} = \frac{D_i}{1.05 R D_o} \quad [39]$$

⁶ This is not exactly true for some of the tubes next to the shell due to the excess area in the head near the shell. However, Equation [35] is close enough for practical purposes.

Again, using Shepherd's optimum value for R , we obtain

$$\frac{D_i}{D_o} = \frac{D_i}{1.52 D_o} \quad [40]$$

Assuming a mean value for $D_i/D_o = 0.881$, substitution in Equation [40] gives

$$\frac{D_i}{D_o} = 0.58 \quad [41]$$

The entrance and exit losses may now be determined from the coefficients as given by the chart, Fig. 3, and are found to be

$$\text{Entrance loss} = 0.29 \frac{V^2}{2g} \quad [42]$$

FIG. 2 TYPICAL TRIANGULAR TUBE SPACING
(Shaded area enclosed by hexagon is cross-sectional area in head, A_s , available for flow in each tube at entrance and exit.)

FIG. 3 CHART SHOWING VELOCITY-HEAD TRANSITION COEFFICIENTS FOR VARIOUS RATIOS OF CONTRACTIONS AND EXPANSIONS WHICH ARE USED IN PRESSURE-DROP CALCULATIONS

and

$$\text{Exit loss} = 0.44 \frac{V^2}{2g} \quad [43]$$

The total pressure drop for the tube-side fluid is, then, from Equations [34], [42], and [43]

$$\Delta P_t = \frac{V^2}{2g} \left(4f \frac{L}{D_i} + 0.73 \right) \quad [44]$$

For Reynolds numbers usually encountered in practice of from 4000 to 40,000, the friction factor f may be calculated from the expression

$$f = \frac{0.054}{R_t^{0.2}} \quad [45]$$

Substitution of the well-known expression for the Reynolds number and Equation [9] in Equation [45] gives

$$f = 0.0515 \left(\frac{ND_i \mu_i}{W_i} \right)^{0.2} \quad [46]$$

and substitution of Equation [46] in [44] gives

$$\Delta P_t = \left(\frac{0.206 LN^{0.2} \mu_i^{0.2}}{D_i^{0.8} W_i^{0.2}} + 0.73 \right) \frac{V^2}{2g} \quad [47]$$

The velocity in feet per second may be expressed by

$$V = \frac{4W_i}{3600 \pi ND_i^2 \rho_i} \quad [48]$$

Equation [47] gives the pressure drop in feet of fluid flowing. In order to obtain this loss in pounds per square foot we simply multiply by the density. Then substitution of Equation [48] in [47] gives

$$\Delta P_t = \frac{W_i^2}{5.15 \times 10^9 N^2 D_i^4 \rho_i} \left(\frac{0.206 LN^{0.2} \mu_i^{0.2}}{D_i^{0.8} W_i^{0.2}} + 0.73 \right) \quad [49]$$

The power required is the product of the pressure in pounds per square foot times the volume of fluid flowing. Therefore the tube-side hourly requirements for power are from Equations [49] and [48]

$$\text{Power} = \frac{W_i^3}{5.15 \times 10^9 N^2 D_i^4 \rho_i} \left(\frac{0.206 LN^{0.2} \mu_i^{0.2}}{D_i^{0.8} W_i^{0.2}} + 0.73 \right) \quad [50]$$

Equation [50] can be simplified by letting

$$\gamma = \frac{W_i^3}{5.15 \times 10^9 \rho_i} \quad [51]$$

and

$$\theta = \frac{0.206 \mu_i^{0.2}}{W_i^{0.2}} \quad [52]$$

Substitution of Equations [51], [52], [30], and [31] in [50] gives the final equation for power rate in foot pounds per hour

$$\text{Power} = \frac{\gamma L^{10}}{D_i^4 C^{10} (\beta D_i^{0.8} + \alpha D_o^{0.8})^{10}} \left[\frac{\theta C (\beta D_i^{0.8} + \alpha D_o^{0.8})}{D_i^{0.8}} + 0.73 \right] \quad [53]$$

The entrance and exit losses from nozzle to head are neglected in the foregoing development, since these losses are independent of tube size. Therefore the optimum tube size is not affected.

FIG. 4 CHART SHOWING VARIATION IN TOTAL ANNUAL COST WITH TUBE DIAMETER FOR VARIOUS FIXED TUBE LENGTHS AS THE PARAMETER

DESIGN PROCEDURE

It is now seen that for a given set of fixed design conditions, the required area and power can be calculated directly from Equations [33] and [53] with the use of only two variables, namely, the length and size of tube. Therefore for any convenient chosen length we can calculate directly a set of values of the area and of the power requirements for a range of tube sizes.

Fixed charges on the initial investment and annual power costs vary with the type of plant and the location. For example, the annual write-off may be, say, 0.75 dollars per square foot per year, and the annual power cost may be 30 dollars per horsepower-year. In this event, then, the total annual cost will be

$$S = 0.75 A + 30.00 \left(\frac{\text{Power}}{60 \times 33,000} \right) \quad [54]$$

Using Equations [33], [53], and [54], we can calculate and plot a curve of total annual cost versus tube size for a particular length of tube (see Fig. 4). If desired, curves can be calculated and plotted for other lengths, each of which will have a well-defined minimum, or if so desired, the optimum length of tubes can be determined for a particular size of tube. Fig. 4 has been plotted to illustrate the comparison of the minimum total annual costs for various optimum sets of tube-length and size combinations. The power cost should of course be based on output of the blower or compressor.

ACKNOWLEDGMENT

The author hereby gratefully acknowledges the helpful suggestions of the engineers of the Chemical Construction Corporation. The author also wishes to thank Mr. E. S. Roberts, chief engineer, Chemical Construction Corporation, for permission to publish this paper.

Discussion

G. M. DUSINBERRE.⁷ It is unfortunate that this paper does not include a bibliography, only three references being given in the footnotes. There is a great deal of previous work along the present line. It would be of interest if the author would show the advantages of his analysis over earlier ones, especially those which use Stanton number and L/D ratio. The author's Fig. 4 shows nearly a constant L/D , affected slightly by the entrance and exit losses which are ignored in some analyses.

D. G. SHEPHERD.⁸ This paper is a useful addition to the scanty literature available on the application of heat-transfer data to a practical design. To anyone not actively engaged in the heat-transfer field, the specific physical data available seem overwhelming and, although a considerable amount of correlation has been achieved and presented, the problem of designing the optimum form of heat exchanger for a given duty is formidable. Where the performance of the exchanger is critical with respect to the power loss, then the optimum design requires a large number of trial-and-error solutions, as initially there may be a choice of crossflow or counterflow, followed by innumerable choices of tube size, arrangement, and spacing.

Such a paper as that of the author is useful in showing how the many variables may be combined to at least direct the calculations toward an optimum design for a particular desired result. It is recognized that any such analysis will be approximate because of the simplifying assumptions which have to be made to obtain an assimilable expression. Nevertheless such analyses can be very valuable to the engineer who does not have a wealth of empirical data and experience at his command.

Inasmuch as the author has used some material from a previous paper of the writer, the latter feels bound to emphasize the limitations pertaining to their use. In Equation [25] of the paper, the author has substituted an optimum value of R of 1.45, where R is the ratio of tube spacing to outside tube diameter. As derived by the writer, this value was for a particular set of conditions pertaining to a gas-turbine heat exchanger with equal air and gas-flow rates and was intended to be illustrative only. It seems unlikely that this particular value of R has general validity.

Again, in Equation [45], a value of the friction coefficient f is given as a simple function of Reynolds number, and this too is likely to be valid only for conditions pertaining to a typical gas-turbine exchanger with small tubes of a given degree of roughness.

AUTHOR'S CLOSURE

Most of the previous work on the economical sizing of a tubular heat exchanger has been confined to topics such as the optimum velocity in the tubes⁹ and the optimum ratio of capital charges to power costs¹⁰ for a fixed tube diameter and tube pitch. The aim

⁹ "Optimum Operating Conditions for Pipe Heat and Cooling Equipment," by W. K. Lewis, J. T. Ward, and E. Voss, *Industrial and Engineering Chemistry*, vol. 16, 1924, pp. 467-468.

¹⁰ "The Design of Heat Exchangers," by K. Niehus, *The Brown Boveri Review*, vol. 28, 1941, pp. 228-232.

of the present paper has been to work with fixed design conditions, over which the designer or manufacturer of the tubular exchanger has no control, and, by the development, to show the effect of the length of tube as well as the diameter of tube upon the optimum design.

If we neglect the end losses, Equation [54] of the paper may be easily differentiated and solved for the optimum L/D ratio. Thereupon substitution in Equation [32] will give the optimum area and, subsequently, the optimum over-all heat-transfer coefficient. However, since this is the subject for a future paper, the details will be omitted here.

The value of R is quite arbitrary, and any convenient value could have been used for the purpose of illustrating the method. The Tubular Exchanger Manufacturers Association gives a minimum value for R of 1.25. The maximum value in practice is around 1.5. If fouling is excessive on the shell side even a larger value may be used.

The only factors affected in the final equations by the R -value are the β -value and the numerical constant in Equation [53] which in this case is 0.73. The variation of the latter figure with $1/R$ is a straight-line relationship and may be represented by

$$E = 2 - \frac{1.84}{R}$$

where E is to be substituted in place of the constant 0.73 in Equation [53]. Any suitable R -value may then be used.

The effect of R on the β -value is given by Equation [25]. It must be remembered, however, that the numerical constant (0.0263) in Equation [25] is a purely theoretical value and that in practice, using an exchanger of the type illustrated, the actual value of this constant will be much higher due to the crossflow at the entrance and exit. This value can be calculated from operating data.

Furthermore, for the special case of a gas in the tubes and a liquid or condensing vapor in the shell, the tube-side film coefficient is controlling and Equation [32] becomes simplified to

$$A_i = \left[\frac{1}{\pi L} \right]^4 \left[\frac{Q D_i}{\alpha \Delta t_{LM}} \right]^5$$

Another point to be borne in mind is that the present paper applies only to a gas-to-gas tubular heat exchanger with triangular tube spacing. Liquid-to-liquid exchangers or in-line tube arrangements would require a similar but separate development.

Equation [45] of the paper is a direct consequence of the Reynolds analogy between heat transfer and pressure drop, i.e.

$$j = f/2$$

where

$$j = \frac{h_i}{C_{pi} G_i}$$

and h_i is defined by Equation [8], using a mean value of 0.78 for the Prandtl number. The limitations of Equation [45] of course are given in the text, but the application in this range is quite general.

Loss Coefficients for Abrupt Changes in Flow Cross Section With Low Reynolds Number Flow in Single and Multiple-Tube Systems

By W. M. KAYS,¹ STANFORD, CALIF.

In testing for the flow-friction characteristics of compact heat-exchanger surfaces concurrent with heat-transfer tests, more precise data on the flow contraction- and expansion-loss coefficients are required than are presently available in the literature. This paper presents a theory for evaluating these coefficients for both single- and multiple-tube systems for various contraction and expansion geometries. The analysis takes into account the contraction and expansion area ratio and the velocity distribution. Results of experiment for the Reynolds number range 500-20,000 are presented which compare well with the analysis. This paper was originally presented at the June, 1949, meeting of the Heat Transfer and Fluid Mechanics Institute, and included only experimental data on multiple-tube systems. Since that time experiments have been performed on single-tube systems and these later results are presented here.

NOMENCLATURE

The following nomenclature is used in the paper:

- A = cross-sectional area of flow tube, sq ft
- C_c = jet contraction-area ratio, dimensionless
- f = Fanning friction factor, dimensionless
- g = proportionality factor in Newton's second law, $g = 32.2$ (lb/#) (ft/sec²)
- K_c = contraction-loss coefficient, dimensionless
- K_e = expansion-loss coefficient, dimensionless
- K_{eb} = kinetic-energy velocity-distribution coefficient, dimensionless
- K_d = momentum velocity-distribution coefficient, dimensionless
- N_R = Reynolds number ($4r_h V \rho / \mu$), dimensionless
- n = number of small tubes in multiple-tube system
- P = static pressure, #/ft²
- r_h = flow-tube hydraulic radius, ft
- r_0 = radius of circular tube
- V = velocity, fps
- x, y = co-ordinates perpendicular to direction of flow
- y_0 = one half distance between two parallel planes
- Δ = as a prefix to P , denotes pressure difference
- ρ = density, lb/ft³

- σ = contraction and expansion area ratio, dimensionless
- μ = viscosity, lb/(hr ft)
- lb = denoting pounds mass in distinction to
- # = denoting pounds force
- \cong = denotes approximately equal

INTRODUCTION

There are many flow problems in which it is necessary to evaluate the losses of mechanical energy at abrupt changes in flow cross section. For incompressible or low Mach number flow, these losses are generally evaluated by the use of expansion and contraction coefficients K_e and K_c , which may be defined as follows, using the nomenclature in Fig. 2

$$\left(\frac{\Delta P}{\rho} \right)_{\text{(expansion loss)}} = K_e \frac{V_1^2}{2g} \dots \dots \dots [1]$$

$$\left(\frac{\Delta P}{\rho} \right)_{\text{(contraction loss)}} = K_c \frac{V_2^2}{2g} \dots \dots \dots [2]$$

(In all equations P refers to static pressure.)

The expansion coefficient K_e is generally evaluated from the Borda-Carnot equation for the pressure loss at an abrupt expansion (which may be derived from momentum considerations)

$$\left(\frac{\Delta P}{\rho} \right)_{\text{(expansion loss)}} = \frac{(V_2 - V_1)^2}{2g}$$

Then

$$K_e = (1 - \sigma)^2$$

This equation, expressing K_e as a function of the expansion-area ratio only, has been verified experimentally for fully turbulent flow ($N_R > 10,000$), by Schutt (1).²

The contraction coefficient K_c , as presented in the literature, is strictly empirical. It is also expressed as a function of the contraction-area ratio only. The K_c coefficients given in the literature are not consistent; for instance, Rouse (2) gives one tabulation of values, while McAdams (3) gives a curve for K_c which differs up to 75 per cent from the data of Rouse.

For most pipe-line problems, the pressure losses at abrupt changes in flow cross section are minor relative to the skin-friction losses. Therefore any question as to the validity of the idealizations involved in the Borda-Carnot analysis, or from the inconsistency of the data on K_c , is of minor importance. However, in testing for the flow-friction characteristics of compact heat-exchanger surfaces concurrent with heat-transfer tests, the entrance and exit losses may become a significant proportion of the total pressure drop (11). When using a gas, the Reynolds

Combining with the definition of K_c , Equation [1]

$$K_c = 1 - 2K_{d1}\sigma + \sigma^2(2K_{d1} - 1) \dots [6]$$

This expression is perfectly general and applies for either single- or multiple-tube expansions. If the velocity distribution is uniform, K_{d1} is equal to unity and Equation [6] reduces to the Borda-Carnot relation

$$K_c = (1 - \sigma)^2$$

As will be shown later, K_{d1} is a function of Reynolds number and flow-tube geometry and approaches unity as Reynolds number is increased. For many multiple-tube expansions, Reynolds number in the large tube is very much greater than in the smaller tubes, and it is sufficiently accurate to assume uniform velocity distribution in the large tube, or K_{d1} equal to unity. Equation [6] can then be reduced to

$$K_c \cong 1 - 2K_{d2}\sigma + \sigma^2 \dots [7]$$

This equation has the advantage that, for multiple-tube systems, K_c can be plotted as a function of σ with N_R in the smaller tubes as a parameter. The error introduced in the use of Equation [7] rather than Equation [6] is $2\sigma^2(K_{d1} - 1)$. If this term is of sufficient magnitude to warrant its inclusion, it can be added to the value of K_c taken from a plot of Equation [7]. K_{d1} can be determined from N_R in the larger tube which is related to N_R in the smaller tubes, for the circular-tube system, as

$$N_{Rd}/N_{Re} = \sqrt{n}\sigma$$

Similar expressions may be derived for other geometries.

Abrupt Contraction Loss. The abrupt contraction system is described in Fig. 2 as section *a* to 3. The flow stream experiences an initial contraction to A_1 and then a re-expansion to A_2 . The losses of flow-stream mechanical energy occur in the region of flow deceleration near the stagnation point, Fig. 2, in the larger tube, and in the region of re-expansion within the smaller tube, or tubes. The former is of secondary importance, and conservation of mechanical energy is assumed in the contraction from A_1 to A_2 . The jet contraction ratio, $C_c = A_2/A_1$, is a function of σ and is evaluated for certain elementary geometries in a later section. Because of the nozzle-like flow up to the "throat" section, A_2 , the velocity distribution at A_2 is assumed to be essentially uniform. However, in applying the energy equation from A_1 to A_2 the nonuniform velocity distribution at A_1 must be taken into consideration by use of a kinetic-energy correction factor K_{e1} , similar to the momentum correction factor, K_{d1} . With the state of the stream at A_2 completely determined, the losses due to the re-expansion can be determined by a momentum analysis identical to that used for the abrupt expansion. The resulting expression for K_c for incompressible flow is

$$K_c = \frac{1 - K_{e1}\sigma^2 C_c^2 - 2C_c + C_c^2 2K_{d1}}{C_c^2} - (1 - \sigma^2) \dots [8]$$

where

$$K_{e1} = \frac{1}{A} \int_0^A \frac{V^3}{V_{av}^3} dA \dots [9]$$

Equation [8] is applicable to either single- or multiple-tube contractions. However, as was the case for the expansion coefficient, a considerable simplification is possible for many multiple-tube applications, and K_c can be expressed as a function of only two variables. Assuming uniform velocity distribution in the large tube, and thus $K_{d1} \cong 1.00$

$$K_c \cong \frac{1 - 2C_c + C_c^2(2K_{d2} - 1)}{C_c^2} \dots [10]$$

The difference between Equations [8] and [10] is $\sigma^2(K_{e1} - 1)$. If the magnitude of this term is sufficient to warrant its inclusion it can be subtracted from the value of K_c taken from a plot of Equation [10].

Evaluation of C_c , K_{d1} , and K_{d2} . Since section *a* to A_2 is a region of flow acceleration, with the exception of the immediate vicinity of the stagnation point, the flow pattern should be fairly well approximated by the pattern for an inviscid fluid flowing through an orifice. This pattern has been determined analytically for two-dimensional flow, and the resulting contraction ratio, $C_c = A_2/A_1$, is tabulated as a function of σ in reference (2).

According to this reference, C_c for the two-dimensional system can be used with good approximation for the three-dimensional circular-tube system if σ for the two-dimensional case is replaced by $\sqrt{\sigma}$ for the three-dimensional case. The extension of this coefficient to the multiple-circular-tube system needs justification. It is for the purpose of checking such assumptions that these tests were made on a multiple-circular-tube system. C_c as a function of σ , from reference (2), is given in Fig. 3 for the two-dimensional and three-dimensional circular contraction situations which approximate the heat-exchanger core contractions shown in Fig. 1.

K_{d1} may be evaluated from Equation [4], providing velocity-distribution data are known. Such data are presented here, Fig. 3, for flow in circular tubes, flow between parallel planes (infinitely wide gap), flow in equilateral-triangular tubes, and square tubes. These are the four geometries to be considered specifically in this analysis.

For laminar flow, the well-known parabolic velocity distribution in the circular tube and in the infinitely wide gap yields values for K_{d1} from the defining Equation [4] of 1.333 and 1.200, respectively. The laminar-flow velocity distribution for the square tube and the triangular tube can be determined by integration of the differential equation for laminar flow

$$\frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} = \text{const.} \dots [11]$$

FIG. 3 C_c FOR THREE-DIMENSIONAL CIRCULAR-TUBE CONTRACTION AND TWO-DIMENSIONAL CONTRACTION AND K_{d1} VERSUS N_R FOR FOUR TYPES OF TUBE GEOMETRY

This integration has been performed by finite-difference methods in reference (5) for the square tube, and the resulting value for K_d from Equation [4] is 1.39. The solution for V is also available in algebraic form (6). For an equilateral triangle, an algebraic solution for V can be obtained (6). The differential equations for laminar-flow velocity distribution and for the stress function for elastic torsion are identical. Consequently, the solution of Saint Venant (6) is applicable.

$$V = -C \left[\frac{1}{2} (x^2 + y^2) - \frac{1}{2a} (x^3 - 3xy^2) - \frac{2}{27} a^2 \right] \quad [12]$$

C and a are constants which cancel out of the solution for K_d from Equation [4]. The resulting magnitude of K_d is $10/7 = 1.43$.

For turbulent flow, semiempirical velocity-distribution data are available for the circular tube and the infinitely wide gap as a function of the friction factor. From reference (2) the modified Kármán-Prandtl relations are as follows

For circular tubes

$$V = V_{avg} \left[\sqrt{4f} \left(2.15 \log_{10} \frac{y}{r_0} + 1.43 \right) + 1 \right]$$

For the gap

$$V = V_{avg} \left[\sqrt{4f} \left(2 \log_{10} \frac{y}{y_0} + 0.88 \right) + 1 \right]$$

Substitution of these expressions into the defining Equation [4] yields the following:

For circular tubes

$$K_d = 1.09068 (4f) + 0.05884 \sqrt{4f} + 1 \dots \dots [13]$$

For the gap

$$K_d = 0.750 (4f) + 0.024 \sqrt{4f} + 1 \dots \dots [14]$$

Equations [13] and [14], together with $f = 0.049 N_{Re}^{-0.2}$, were employed in the preparation of Fig. 3. The friction-factor relation for circular tubes was also used as an approximation for the wide-gap geometry. The coefficient 0.049 was used instead of the usual 0.046 for "smooth" tubes (3), as being more applicable to the heat-exchanger surfaces under consideration.

Also plotted in Fig. 3, are the laminar-flow solutions for K_d for all four geometries.

The turbulent flow K_d for the square and triangular cross-section geometries shown in Fig. 3 were estimated from the fact that

$$\frac{K_{d(gap)} - 1}{K_{d(circular)} - 1} \cong 0.6$$

for both laminar and turbulent flow. Therefore it was concluded that the similar ratios

$$\frac{K_{d(square)} - 1}{K_{d(circular)} - 1} = 1.17, \quad \frac{K_{d(triangle)} - 1}{K_{d(circular)} - 1} = 1.29$$

determined from the laminar-flow solutions, would also apply as an approximation for turbulent flow.

K_{e0} may be evaluated from its defining Equation [9] employing the velocity-distribution data just given. This has been worked out only for the circular-tube system. For laminar flow, $K_{e0} = 2.00$. For turbulent flow, the following equation obtains

$$K_{e0} = -1.735 (4f)^{1/2} + 3.272 (4f) + 0.0883 (4f)^{1/3} + 1 \dots [15]$$

Graphs of K_e and K_{e0} . Employing Equations [7] and [10], in conjunction with the data given in Fig. 3, the expansion and con-

traction coefficients have been evaluated for the four basic flow-tube geometries with multiple expansions and contractions, and are presented in Figs. 4, 5, 6, and 7. C_e for the two-dimensional contraction was used for the gap, square, and triangular geometries, Figs. 5, 6, and 7. Since the fins forming the square tubes, Fig. 1(b), are assumed to be very thin, the two-dimensional data are applicable. For the triangular tubes, however, there may be some question as to the validity of this assumption since the fins would be expected to interfere to a certain extent with the two-dimensional contraction.

For the single circular tube contraction and expansion, Equations [6] and [8] can be used directly. Alternatively, Fig. 4 can be used in conjunction with the corrections previously indicated relating the approximate Equations [7] and [10] to [6] and [8], respectively. Reynolds number in the large tube is always less than Reynolds number in the small tube so that the velocity distribution in the large tube must be taken into consideration. An interesting consequence arises here in that the transition from laminar to turbulent flow in the two tubes takes place at different mass-flow rates. Since there is a large change in K_e and K_{e0} at this transition (see Fig. 3), two discontinuities in K_e and K_{e0} result, corresponding to the transitions between the three possible flow conditions—both tubes laminar, one laminar and the other turbulent, and both turbulent. These two discontinuities are confirmed by the tests of a single-circular-tube contraction and expansion presented here.

Examination of Figs. 4, 5, 6, and 7 results in the following conclusions for the multiple-tube system: (a) In all cases the effect of decreasing Reynolds number is to decrease the expansion coefficient and increase the contraction coefficient, and this effect is much more marked for the flow passages with sharp corners than for the circular tubes or the infinitely wide gap. (b) In all cases there is a large change of magnitude of the coefficients from turbulent to laminar flow. (c) It is possible to have a negative "loss" coefficient K_{e0} for some cases of high σ if $K_{d0} \gg K_{d1}$, as is implied in the use of Equation [7]. This results from the fact that K_e is defined on the basis of bulk average velocities. (d) Even with area ratios of unity (which is approached as a limiting case in some types of finned-flat-tube intercooler and automobile radiator surfaces), instead of a zero loss coefficient as may be superficially expected, it is possible to have a negative loss coefficient K_{e0} for the reason given in the foregoing.

Application to Heat-Exchanger Test Cores. The curves in Fig. 7 are based on a two-dimensional contraction and velocity distribution in the smaller tubes characteristic of an equilateral-triangular flow section. These data should apply as a good approximation of flow passages such as shown in Fig. 1(c) even if the flow passages are narrow isosceles triangles. The velocity-distribution coefficient for these passages would not be expected to differ markedly from that of an equilateral triangle, and further, the fins would offer but slight interference to the two-dimensional contraction. Likewise the data in Fig. 6 should apply to rectangular flow passages such as shown in Fig. 1(b).

For most multiple-tube heat-exchanger systems, the transition from laminar to turbulent flow takes place smoothly over a range of Reynolds numbers because of the variations of tube geometry inherent in the manufacturing methods employed. This transition range can be detected from the heat-transfer performance of a test system, and then the expansion and contraction coefficients can be evaluated approximately by connecting the curves for laminar- and turbulent-flow coefficients by a smooth curve over the indicated range.

These coefficients have been evaluated for continuous non-interrupted tubes. For tubes with flow-interrupting louvers, as shown in Fig. 1(c), or with other types of discontinuous fins, the coefficients would not be expected to vary so markedly with

Reynolds number, because marked variations in velocity distribution are prevented from occurring. For very short strip fins, or pin fins, it is recommended that the coefficients for $N_R = \infty$ be employed for all Reynolds numbers.

EXPERIMENTAL RESULTS

In order to verify the applicability of the analytically evaluated expansion and contraction coefficients to actual systems, experiments were performed on the following systems:

- 1 A single circular-tube contraction and expansion system at two contraction and expansion area ratios.
- 2 A multiple circular-tube contraction and expansion at various area ratios.
- 3 A multiple triangular-tube contraction and expansion at one area ratio. This geometry is similar to that of a typical plate-fin heat-exchanger surface, Fig. 1(c).
- 4 A system similar to that of item 3 using interrupted, or louvered fins, Fig. 1(c).

Description of Test Apparatus. Water was employed as the flow medium for the single circular-tube test system. For the multiple-tube test system air was used. Although the analysis is based on an incompressible fluid, the Mach number in the tubes did not exceed 0.2, so that compressibility effects were small except for several of the test runs of system 3.

The two test systems consisted of a brass tube cut and flanged at the test section so that cores containing the single or multiple smaller tubes could be inserted, thus forming an abrupt contraction followed by an abrupt expansion. Sufficient pressure taps were provided in both the approach and discharge ducts and in the test cores so that static pressure could be determined as a function of length, as shown in Fig. 2.

For the single-tube test system, the water was metered gravimetrically, and static pressures were measured by a bank of manometers using carbon tetrachloride under water. Flow regulation from a constant-head supply tank was accomplished by adjustment of three needle valves in parallel.

FIG. 7 CONTRACTION AND EXPANSION COEFFICIENTS FOR MULTIPLE-TRIANGULAR-TUBE PLATE-FIN SYSTEM

For the multiple-tube test system, the air was metered by a standard flat-plate orifice meter using the coefficients of reference (7). Static pressures were measured by a system of inclined draft gages and vertical single-leg water manometers. Flow-rate control from an automatic pressure regulator was accomplished by two manually controlled needle valves in parallel.

The single circular-tube test cores were constructed of brass tubing with four holes drilled and connected by a piezometer ring for each static-pressure tap.

The multiple-circular-tube test cores were constructed by drilling 19 tubes through a solid aluminum core. The static pressure taps each intersected three of the tubes. The plate-fin test core was built up of brass plates with inserts of fin material. The static pressure taps each intersected six flow tubes.

The pressure losses due to the contraction and expansion were evaluated by extrapolating the straight-line pressure variations to the point of abrupt change in flow cross section, as shown in Fig. 2. The contraction and expansion coefficients were then evaluated from Equations [1] and [2].

A more detailed description of the test systems, the original test data, and the method of analysis are contained in references (9) and (10).

Results of Tests. Figs. 8 through 13 show the experimentally determined expansion and contraction coefficients plotted as a function of Reynolds number in the smaller tube, or tubes. Denoted by dashed lines are the coefficients as predicted by the preceding analysis.

The results for the single-circular-tube system for one area ratio are shown in Figs. 8 and 9. Except for the contraction coefficients K_c at the lowest Reynolds numbers, the agreement between analysis and experiment is excellent. The poorer agreement for K_c at low Reynolds numbers is attributable to the poor experimental accuracy at low flow rates. The results of these tests illustrate clearly the double transition, especially in the case of the contraction coefficients where the effect is more pronounced.

Fig. 10 shows the expansion coefficients for four expansion-area ratios in the multiple-circular-tube system. Although there is a considerable scattering of test points, especially at the lowest Reynolds number, where the measured pressure changes were only a few hundredths of an inch of water, the analytically evaluated coefficients appear to be well substantiated by experiment. Because of the limitations of pressure-measurement accuracy, it was not possible to test at sufficiently low Reynolds numbers to substantiate completely the laminar-flow analysis, but the trend toward the laminar-flow curve is definitely evident.

Fig. 11 shows the contraction coefficients for two area ratios in the multiple-circular-tube system. Here the analytically evaluated coefficients are well substantiated for Reynolds numbers above 12,000. The behavior of the experimental coefficients at Reynolds numbers below 12,000 is believed to be due to the relatively short flow lengths in the test cores. The length-to-diameter ratio for these two test cores was 25.5 and 16.0, respectively, as compared to 100 for the single-circular-tube system. In order to evaluate the contraction coefficients it was necessary to extrapolate the pressure variation in the test core back to the entrance (see Fig. 2), and thus for accurate results, flow characteristic of long tubes would have to be established fully in at least one half the length of the core. It is evident that for the short-tube test cores, the fully developed laminar flow would never be established, and that fully developed turbulent flow would not exist until fairly high Reynolds numbers were reached.

Fig. 12 shows the results of tests of the plate-fin core with plain fins. Here the flow length was again sufficiently long to obtain good contraction-coefficient data at low Reynolds number, but below $N_R = 1000$ the experimental accuracy deteriorates rapidly. Nevertheless, the laminar-flow coefficients from Fig. 7 agree with the trend of the experimental results. At Reynolds numbers above 6000, both the contraction and expansion coefficients tend to decrease and drop away from the analytically evaluated coefficients. Here Mach number > 0.15 and the compressibility effects become significant. The coefficients K_c and K_e , since they are defined for incompressible flow, lose rigorous significance for compressible flow. However, it can be demon-

strated on the basis of the data of reference (8) that the compressibility effect will be to decrease the "apparent" coefficients in the manner shown by the experimental results. For Mach number < 0.15 , the incompressible-flow treatment applies with good accuracy for most applications.

Fig. 13 shows the results of tests of the plate-fin core with interrupted fins. The very marked variation of the coefficients K_c and K_e with Reynolds number is no longer evident due to the tendency of the louvers to minimize large changes in velocity distribution with variations in N_R . The louvers have their greatest effect at Reynolds numbers below 2000 where the parabolic velocity distribution with a large K_d characteristic of laminar flow ordinarily would occur. The failure of the contraction coefficients K_c to approach closely the predicted curve (from Fig. 7 for smooth fins) at the higher Reynolds numbers is probably attributable to the actual system departure from the postulated two-dimensional contraction. This departure may be caused by the interference of the fins owing to curvature both in the plane of the flow and normal to the flow.

SUMMARY AND CONCLUSIONS

The results and conclusions of the foregoing analytical and experimental investigation may be summarized as follows:

- 1 A theory is developed for the prediction of contraction and expansion coefficients for essentially incompressible flow.
- 2 The theory for the expansion coefficient is an extension of the Borda-Carnot analysis allowing for nonuniformity of velocity distribution at both the upstream and downstream sections.
- 3 The theory for the contraction coefficient is an extension of the expansion-coefficient analysis. The loss of mechanical energy is considered to take place during the re-expansion after an initial contraction to a vena contracta inside the smaller tube, or tubes.
- 4 The specific application of this theory requires velocity-distribution data at both sections in question and, for the flow-contraction problem, additionally requires the area contraction ratio for the vena-contracta section.
- 5 The velocity-distribution coefficient can be obtained analytically for laminar flow in cylinders. For turbulent flow, data are available for application to the circular tube and two-dimensional flow between parallel planes. The square and triangular tubes are treated approximately.
- 6 Application of the idealized system analysis to geometries corresponding to some high-rating heat-exchanger surfaces is indicated.
- 7 Experimental results substantially confirm the predictions of the analysis. Discrepancies can be rationalized in terms of the departure of test system and idealized system geometries, and additionally in terms of experimental accuracies.

These data have been used to extract friction factors from over-all pressure-drop measurements in testing plain plate-fin heat-exchanger cores. The fact that in a typical case the friction factors are 16 per cent lower for laminar flow and 10 per cent lower at $N_R = 10,000$, when these coefficients are used in place of the conventional data, illustrates the necessity for accurate contraction and expansion coefficients for this type of work (11).

ACKNOWLEDGMENTS

This work was accomplished under the sponsorship of the Office of Naval Research on Navy Contract N6-ONR-251, Task Order VI, at Stanford University. The co-operation of the Office of Naval Research in permitting the results of this work to be presented is acknowledged.

The experimental work on the single circular tube system was accomplished by Mr. Paul G. Bissiri, who also contributed the ex-

tension of the analysis to account for the double transition in the single-tube system.

Heat-Transfer and Flow-Friction Characteristics of Some Compact Heat-Exchanger Surfaces

Part 1—Test System and Procedure

By W. M. KAYS¹ AND A. L. LONDON,² STANFORD, CALIF.

This paper describes a test apparatus and method of analysis used for the accurate determination of the basic heat-transfer and flow-friction characteristics of compact heat-exchanger surfaces. The experimental accuracy is discussed and the results of test of a typical louvered-plate-fin heat-exchanger surface are included to illustrate the quality of data obtainable. It is hoped that the experience presented here may lead to a standardization of test methods so that more accurate design data will be forthcoming.

NOMENCLATURE

English Letter Symbols:

The following nomenclature is used in the paper:

- A = test-core total air-side heat-transfer area, ft^2
- A_c = test-core free-flow area, ft^2
- A_f = test-core extended-surface area, ft^2
- A_s = test-core total steam-side heat-transfer area, ft^2
- A_w = test-core direct-surface heat-transfer area, ft^2
- c_p = specific heat at constant pressure, $\text{Btu}/\text{lb } ^\circ\text{F}$
- D_d = hydraulic diameter of test duct, ft
- f = Fanning friction factor, dimensionless
- f_d = test-duct friction factor, dimensionless
- G = test-core mass velocity, $\text{lb}/(\text{hr ft}^2 \text{ of } A_s)$
- g = proportionality factor in Newton's second law, $g = 32.2$ (lbs/ft^3) (ft/sec^2)
- h = unit conductance for thermal-convection heat transfer, $\text{Btu}/(\text{hr ft}^2 ^\circ\text{F})$
- h_s = unit conductance for steam-side surface, $\text{Btu}/(\text{hr ft}^2 ^\circ\text{F})$
- K_c = contraction loss coefficient for flow at heat-exchanger entrance, dimensionless
- K_e = expansion loss coefficient for flow at heat-exchanger exit, dimensionless
- k = unit thermal conductivity, $\text{Btu}/(\text{hr ft}^2 ^\circ\text{F}/\text{ft})$
- k_w = unit thermal conductivity of wall material, $\text{Btu}/(\text{hr ft}^2 ^\circ\text{F}/\text{ft})$
- L = total flow length of test core, ft
- l = effective fin length, ft
- l_d = length of test duct between test core and pressure taps, ft
- l_w = wall thickness, ft
- $m = \sqrt{2h/k\delta}$, $1/\text{ft}$

- P = pressure, lb/ft^2
- r_h = flow passage hydraulic radius, ft
- T = temperature, $^\circ\text{R}$
- t = temperature, $^\circ\text{F}$
- U = unit over-all thermal conductance, $\text{Btu}/(\text{hr } ^\circ\text{F ft}^2 \text{ of } A)$
- v = specific volume, ft^3/lb
- w = air-mass flow rate, lb/hr

Greek Letter Symbols:

- Δ denotes temperature difference or, followed by P , denotes pressure difference
- δ = fin-metal thickness, ft
- ϵ_h = error in Stanton number determination, per cent
- ϵ_2 = error in core downstream temperature difference, $^\circ\text{F}$
- η_f = temperature effectiveness of fins, dimensionless
- η_o = over-all temperature effectiveness of a plate-fin surface, dimensionless
- η_s = over-all temperature effectiveness of steam-side surface, dimensionless
- ρ = air density, lb/ft^3
- σ = ratio of free-flow to frontal area of test core, dimensionless
- μ = air viscosity, $\text{lb}/(\text{hr ft})$
- μ_f = air viscosity, evaluated at a "film average" temperature, $\text{lb}/(\text{hr ft})$

Dimensionless Groupings:

- N_{St} = Stanton number, (h/Gc_p) , a heat-transfer modulus
- N_{Pr} = Prandtl number, $(\mu c_p/k)$, a fluid-properties modulus
- N_R = Reynolds number, $(Ar_h G/\mu)$, a flow modulus
- $N_{St} N_{Pr}^{1/3}$ = generalized heat-transfer grouping. This factor versus N_R defines heat-transfer characteristics of surface
- f = Fanning friction factor. This factor versus N_R defines friction characteristics of surface
- NTU = number of heat-transfer units, a heat-transfer parameter, (AU/wc_p)

Subscripts:

- O = duct conditions upstream of test core
- 1 = conditions at test-core entrance
- 2 = conditions at test-core exit
- 3 = duct conditions downstream of test core
- s = steam-side conditions
- f = film average conditions

Miscellaneous:

- lb denotes pounds mass in distinction to
- $\#$ denoting pounds force

INTRODUCTION

Until quite recently, the only accurately known basic heat-transfer and flow-friction data for application to heat-exchanger

¹ Acting Instructor, Mechanical Engineering, Stanford University. Jun. ASME.

² Professor, Mechanical Engineering, Stanford University. Mem. ASME.

Contributed by the Heat Transfer and Gas Turbine Power Divisions and presented at the Annual Meeting, New York, N. Y., November 27-December 2, 1949, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 49-A-95.

design was for flow through circular tubes and over banks of circular tubes. The advent of the gas turbine as a promising transportation-type prime mover, the development of portable oxygen plants, and the continued emphasis on small size and light weight in aircraft installations have pointed the need for more compact heat exchangers than are practicable utilizing these conventional tubular-type surfaces.

As a matter of definition, the term "compactness" refers to the area-to-volume ratio characteristic of the surface in question. A "compact surface," for the purpose of this paper, is one providing more than 75 ft² of transfer area per ft³ of core volume. This compares to the approximately 20 ft²/ft³ which can be realized from conventional 1-in.-diam tubes.

More compact surfaces can usually be realized by the use of fins, and higher heat-transfer coefficients can be obtained from surfaces employing various types of boundary-layer interruptions. In both cases there are few adequate basic data upon which to base even preliminary designs.

In the design of systems for the exchange of heat between liquids, accurate knowledge of the friction characteristics of the heat-transfer surface is relatively unimportant because of the low cost of pumping high-density fluids. For low-density fluids such as gases, however, the cost of friction per mass unit of flow is greatly multiplied, and thus the friction behavior of the surface becomes as important as the heat-transfer behavior. This is particularly true for the gas-turbine-plant heat exchangers—the regenerator and the intercooler, and especially the former, where the high-temperature, low-pressure exhaust gases are concerned.

It is the purpose of this paper to describe a test apparatus and testing technique which are being currently employed for the accurate determination of the basic heat-transfer and flow-friction characteristics of compact heat-exchanger surfaces in the hope that the experience gained in the design and operation of this system may be of use to others contemplating similar work. The design of this test system was based upon experience gained from a similar system at the U.S.N. Engineering Experiment Station, Annapolis, Md. (1).²

METHODS OF TESTING AVAILABLE

The heat-transfer characteristics of a surface, for application to fluids, with the exception of the liquid metals, can be expressed by the conventional nondimensional relation, $N_{St}N_{Pr}^{1/3}$ versus Reynolds number. The friction characteristics can be generalized using f (Fanning friction factor) versus Reynolds number. Air can be used as a test medium, and the relations given allow extrapolation to any fluid for which the necessary properties are known.

Since the flow-friction characteristics of a heat-exchanger surface, designed for use with gases, are equally as important as the heat-transfer behavior, it is obviously desirable for the sake of economy to have a test system capable of obtaining both characteristics from the same test core. For the compact heat-exchanger surfaces of interest, it is generally not practicable to measure pressures in the actual flow tubes, as can be seen from the typical test core, Fig. 1. Pressures must be measured in the ducting leading to and from the test core and the friction factor extracted from the total pressure drop by taking into consideration the flow losses due to the abrupt contraction and expansion at the entrance and exit to the core. Since the entrance and exit-loss coefficients for complex contractions and expansions are not known very accurately, the entrance and exit losses must be minimized by the use of long flow lengths, or in effect, as large a

² Numbers in parentheses refer to the Bibliography at the end of the paper.

FIG. 1 TYPICAL EXTENDED-SURFACE PLATE-FIN TEST CORE

magnitude of the ratio $(L/4r_h)$, as is consistent with the requirements for accurate evaluation of the heat-transfer behavior.

Both transient and steady-state heat-transfer testing techniques have been used for this type of work. A transient technique has been developed in which it is necessary to measure only the maximum rate of change of temperature of the fluid emerging from an initially uniformly heated core, reference (2). This method has the advantage that a relatively large $(L/4r_h)$ may be employed, and thus the entrance and exit effects can be minimized. A further advantage is that it is not necessary to measure wall temperatures. This method is especially applicable to the determination of the characteristics of closely packed screens and other such surfaces as may find use in the regenerative-type heat exchanger. However, until this transient technique is further refined it is believed that the steady-state methods will yield more accurate data over the useful N_R range for the surfaces considered for this project.

One steady-state method employs a crossflow test core for which the two fluid sides are identical, and equal mass-flow rates of air are used. The over-all heat-transfer conductance can be deduced from the various average terminal temperatures. The unit film conductance of one side can be deduced from the assumption of equal conductances on both sides. The disadvantages of this method are: (a) Since the air leaving both sides has a temperature varying over the flow cross section, some kind of mixer is required. (b) A complicated ducting system is necessary. (c) Only surfaces which can be constructed into completely symmetrical test cores can be tested.

A much simpler steady-state system, without these disadvantages, uses condensing steam on one side of the test core. The steam side is at sensibly uniform temperature with a thermal resistance of generally less than 5–10 per cent of that of the air side. The temperature of the air leaving the test core is essen-

tially uniform on the steam side of the steam. The air side suffers from the same problem because of the same reasons. The methods of measurement of the NTU = UA/C are later, ten accuracy of NTU greater than the successive errors in Fig. 14).

NTU

Thus (L/4r_h) is chosen by the designer to obtain the desired magnitude of error. For example, if L/4r_h = 500 is a reasonable value. At higher values this limit

The value of L/4r_h in Figs. 2 is principally a function of the surface area placed in the flow through the test core. A steady-state steam test system is the one chosen for comparison. This error is accurate

tially uniform over the flow cross section and the type of surface on the steam side is not too important. A reasonable estimate of the steam-side resistance will suffice to determine accurately the air-side unit film conductance. However, this method suffers from definite limitations on the magnitude of $(L/4r_h)$ because of errors introduced into the computed results by limitations of temperature-measurement accuracy. For all the methods described, a dimensionless heat-transfer parameter, $NTU = AU/wc_p$, is ultimately deduced from air-side temperature measurements. For this last method, as will be shown later, temperature-measurement errors will result in maximum accuracy in the over-all conductance, U , if $NTU = 1.00$; and NTU greater than 3, or less than 0.2, will generally result in excessive error in U even with excellent instrumentation (see Fig. 14). NTU is related to $(L/4r_h)$ as follows

$$NTU = \frac{AU}{wc_p} = \frac{A}{A_c} \frac{U}{Gc_p} = \frac{A}{A_c} \frac{h}{Gc_p} = 4 \left(\frac{L}{4r_h} \right) N_{St}$$

Thus $(L/4r_h)$ is limited by the magnitude of Stanton number. However, despite this limitation, this method of testing has been chosen here because of its relative simplicity. Accurate data are obtained by using test cores constructed so that as large a magnitude of $(L/4r_h)$ as possible is employed with $NTU < 3$. For example, Stanton number for air flow in circular tubes at $N_{Re} = 500$ is about 0.010. For an NTU of 3, $(L/4r_h)$ becomes 75. At higher Reynolds numbers, Stanton number decreases so that this limitation applies to the lowest Reynolds number of interest.

DESCRIPTION OF TEST APPARATUS

The various components of the test apparatus are shown in Figs. 2 and 3, and diagrammatically in Figs. 4, 5, and 6. The principal element is an induced controllable-flow air duct with a rectangular test section, $8\frac{3}{4}$ in. \times $9\frac{3}{4}$ in. The exchanger surface under investigation is made into test cores which are placed in the test section. Air-side instrumentation is provided for metering the air, measuring the change in air temperature through the core, and measuring the air pressure drop.

A steam system is provided to supply slightly superheated steam to the test core, and instrumentation is provided so that the energy loss of the condensing steam may be measured and compared to the separately determined energy gain of the air. This energy balance provides a continuous partial check on the accuracy of the instrumentation.

(Air-metering section and blower.)

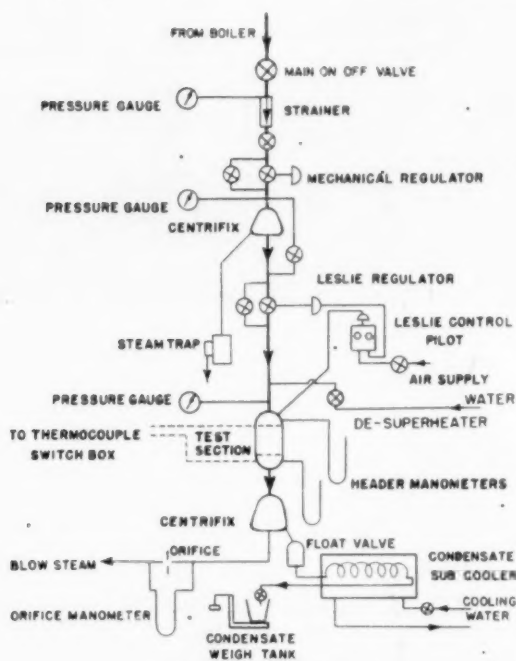

FIG. 6 STEAM SYSTEM

Air System, Figs. 4 and 5. The sheet-metal air duct consists of two sections—one rectangular which includes the test section, the other circular which includes the air-metering orifice.

Air is induced through the duct by a centrifugal blower, rated 5500 cfm at 40 in. of water static pressure. The blower is powered by a 3450-rpm induction motor. Flow regulation is accomplished by a manually operated double sliding plate which con-

stricts the flow symmetrically at the blower intake. With this intake flow control, no pulsation difficulty has been encountered, and smooth regulation is possible from wide open to shutoff. An induced-flow system was chosen to avoid the poor velocity-distribution characteristic of a forced-draft system.

Referring to Fig. 4, room-temperature air is induced into the test duct through a smoothly converging entrance section. A 16-in. axial-flow fan is placed 40 in. before the entrance section. This fan produces a hollow cone of rotating air which encloses the entrance section without blowing directly into it. This serves to mix thoroughly the intake air to a uniform temperature in spite of vertical temperature differences of 2-3 F existing in the laboratory. Following the entrance, the air passes through an "egg-crate" straightening section. The ends of the straightening section form trim tabs which were used to adjust the flow so that the velocity distribution at the test section was close to uniformity for the test range, 400 to 12,000 lb/hr. The results of Pitot-tube traverses, demonstrating this uniformity, are shown in Fig. 7.

The ducting between the entrance and the test section contains, in addition to the straightening section, two 16-mesh wire screens to standardize turbulence, a shielded thermocouple, and four pressure taps connected by a piezometer ring. The last turbulence screen is 18 in. ahead of the test core.

The ducting on the downstream side of the test section is lagged with 1 1/2-in. magnesia insulation plus a double layer of asbestos cloth to reduce radiation errors in the air-temperature measurements. The test core is clamped between 1-in.-thick plastic insulating flanges at the ends of the ducts. Three shielded thermocouples and four pressure taps connected by a piezometer ring are located in the downstream section. The final location of the upstream and downstream pressure taps was determined by a pressure survey, the results of which are shown in Fig. 8.

The air next passes through a transition section and into a circular duct lagged with 1 1/2-in. magnesia. This duct contains a straightening section constructed of 1-in. tubing and an air-

FIG. 7 PITOT-TUBE TRAVERSES UPSTREAM OF TEST CORE

metering orifice with vena-contracta taps. Three orifice sizes are used in order to cover the desired flow range. These meters are standard units, constructed and installed in accordance with the specifications of reference (3), which also provides the orifice coefficients for the flow equation. A shielded thermocouple is located downstream.

Steam System, Fig. 6. Wet steam is generated in a boiler at a pressure which can be regulated from 30 to 100 psig. Steam enters the regulatory system at boiler pressure. It is strained and then passes through a $\frac{1}{4}$ -in. automatic regulator where the pressure is reduced to between 15 and 30 psig. Most of the liquid phase is then removed in a centrifugal separator. The essentially dry vapor is further throttled in an air-operated pilot-controlled regulator to a pressure of approximately 6 psig, and about 10 F of superheat. A small amount of water may be injected at this point to provide close control on the desired 3 to 5 F superheat on entry to the top of the test core. This small degree of superheat is necessary so that the steam state can be fixed by measurements of pressure and temperature only and still maintain essentially uniform temperature conditions on the steam side. The pilot-operated regulator holds the core steam pressure within ± 0.1 in. of mercury, and the corresponding saturation temperature constant within ± 0.17 F.

A considerable excess of "blow" steam is passed through the core to prevent the build-up of a thick film of condensate on the transfer surface. The blow steam and condensate leave the test core via a header at the bottom. Copper wool in the inlet header assures an even steam distribution over the flow cross section. Pressure taps and thermocouples are located in both headers.

Directly below the exit header, the blow steam and condensate enter a centrifugal separator, and then the dry blow passes through a metering orifice before discharge to the atmosphere.

FIG. 8 PRESSURE VARIATION ON EITHER SIDE OF TEST CORE
(This diagram was used to locate piezometer rings.)

The condensate leaves the system by way of a floating-type steam trap and a subcooler where its temperature is reduced to approximately 100 F to avoid flashing during weighing. It then passes into a bucket where the flow rate is measured gravimetrically. The entire system is well insulated to minimize any extraneous heat transfer.

Pressure Instrumentation. Instrumentation is provided for measuring the test-core air-pressure differential, air-orifice pressure differential, gage pressure upstream of the test core and orifice, steam-header gage pressures, and the blow-steam orifice differential. The air pressures are all measured with vertical single-leg-type water manometers or inclined draft gages, and the steam pressures with mercury manometers.

For the steam-pressure manometers, liquid water is used to transmit the pressure to the manometer. This connection is shown in Fig. 9. Condensation and overflow in these "pots" maintain a constant water head on the manometer.

Temperature Instrumentation, Figs. 10, 11. All temperatures are measured with single-junction iron-constantan thermocouples (No. 24 gage wire). The system is designed so that temperatures may be estimated to within 0.2 F. Junctions are formed by an electrowelding process under oil, producing a clean unoxidized bead, approximately $\frac{1}{32}$ in. diam.

The five traversing-type thermocouples in the air stream are mounted in radiation shields as shown in Fig. 10. Together with the insulated duct wall, the calculated effects of thermocouple radiation are negligible.

The pencil-type steam-header thermocouples, Fig. 11, are sufficiently long, and the test-core walls well enough insulated so that the effect of steam conduction is negligible.

A reference junction at approximately 80 F is used. It is immersed in a bakelite tube filled with mercury, which is in turn immersed in a water-filled thermos bottle. The reference-

FIG. 9 STEAM-SYSTEM PRESSURE POTS
(These are used to transmit steam pressure to mercury manometers.)

FIG. 10 RADIATION SHIELDED THERMOCOUPLES
(Used for air-temperature measurements.)

FIG. 11 STEAM-SYSTEM THERMOCOUPLES

junction temperature is obtained from a calibrated standard thermometer, 0.2 F divisions, immersed in the same mercury well.

All thermocouple leads are brought into a single zone box which is thoroughly insulated, and, in addition, two 1/4-in-thick copper plates are placed inside, sandwiching the terminal strip, for the purpose of producing an isothermal zone. Copper leads then connect the selector switch to an electronic self-balancing potentiometer. The potentiometer has a range of 5000 microvolts on a 25-in. scale. The smallest division is 10 microvolts and readings may be estimated to ± 2 microvolts (0.07 F), for the single-junction thermocouples.

The temperature which is the most difficult to measure with the desired accuracy is the bulk average air temperature leaving the test core. Nine-point traverses are made with each of three thermocouples, and Fig. 12 shows the temperature variation for two widely differing air-flow rates for a typical test core. The similarity of the temperature variations indicates that they are due to nonhomogeneity in the core construction and not to instrumentation. The variation from top to bottom can be accounted for by the build-up of steam-side resistance.

All secondary instruments were calibrated against standard

FIG. 12 TEMPERATURE TRAVERSES
(Results for downstream side of typical test core for two air-flow rates.)

instruments. In addition, three continuous checks are provided in the testing procedure, as follows:

- 1 Since the condensate plus blow steam in the bottom test-core header is in the mixed-phase region, its temperature can be determined accurately from the pressure measurement. This saturation temperature is checked against the temperature indicated by the thermocouple in the bottom header.
- 2 An energy balance has been mentioned previously.
- 3 The three orifices are checked one against another by overlapping the test air-flow rates and comparing the results. Any inconsistency in the flow measurement between orifices will then show up as jumps in the friction-factor results.

DESCRIPTION OF TEST CORES

Fig. 13 specifies the test-core dimensions with the exception of the air-flow length which must be determined separately for each surface to realize satisfactory accuracy in the determination of both N_{St} and f . The equation for evaluating the Stanton number from measurements of steam temperature and air-inlet and outlet temperatures, derived from the combination of an energy balance, and the heat-transfer-rate equation, is

equation

$$\frac{(t_1 - t_2)}{(t_1 - t_3)} = \frac{\Delta_1}{\Delta_2} = e^{NTU} = e^{\frac{AU}{\dot{m}c_p}} \quad [1]$$

$$= e^{A(L/Ark)\dot{N}St} \quad [2]$$

The second equation results from the approximation, $U = h$. Since Δ_1 is always greater than Δ_2 , temperature-measurement errors will have the most pronounced effect on Δ_2 . This effect

FIG. 13 TEST-CORE OUTLINE DIMENSIONS

on the Stanton-number determination can be evaluated by treating small errors as differentials. Denoting the per cent error in Stanton number as ϵ_h and the absolute error in Δ_2 as ϵ_2 , the following obtains from Equation [2]

$$\epsilon_h = \frac{\epsilon_2 e^{NTU}}{\Delta_1 NTU} \quad [3]$$

Equation [3] is plotted in Fig. 14 for $\Delta_1 = 150$ F and various magnitudes of error in Δ_2 . It should be noted that the minimum error occurs when $NTU = 1.00$. The use of this plot in the determination of the test-core air-flow length and the limitations which it imposes have already been indicated.

TREATMENT OF DATA

Heat-Transfer Calculations. The effect of the small inlet-steam superheat on the hot-side temperature is negligible. The essentially constant steam-side temperature is evaluated from the average steam-side saturation pressure (the steam-side temperature variation is 0.17 to 0.34 F due to a pressure drop of the order of 0.1 to 0.2 in. Hg). Equation [1] is used to evaluate the over-all conductance from the test data. From U , the air-side unit film conductance h can be extracted using the resistance equation

$$\left(\frac{1}{U}\right) = \frac{A}{\eta_o A_s h_s} + \frac{A}{A_w k_w} + \frac{1}{\eta_o h_o} \quad [4]$$

Over-all resistance Steam-side resistance Wall resistance Air-side resistance

The steam-side unit film conductance, h_s , is required, but as the steam-side resistance is generally less than 5-10 per cent of the total, a reasonable estimate of h_s is all that is necessary. The estimate used is based upon Nusselt's analysis given in reference (4). The other terms in the equation are system constants with the exception of η_o , the temperature effectiveness of the surface ($\eta_o = 1.00$ if there is no extended surface); η_o is related to the temperature effectiveness of the fins alone as follows:

$$\eta_o = \frac{A_w + \eta_f A_f}{A}$$

FIG. 14 ERROR IN STANTON NUMBER RESULTING FROM TEMPERATURE-MEASUREMENT ERRORS

For fins of constant conduction cross section and convection periphery

$$\eta_f = \frac{\tanh ml}{ml}$$

where $m = \sqrt{2h/k\delta}$, and l is one half the total fin length. For other fin geometries, the information of reference (5) may be used.

All the dry-air properties are taken from reference (6). N_{Pr} and μ are taken as for dry air, but for c_p used in N_{St} , as well as the density in the flowmetering calculations, an adjustment is made for atmospheric humidity.

Friction-Factor Calculations. The core pressure drop as measured is considered to consist of the following components:

- 1 A pressure drop on air-flow entrance to the core, ΔP_{a-1} .
- 2 A core-friction and flow-acceleration pressure drop, ΔP_{core} .
- 3 A pressure recovery on air-flow exit from the core, ΔP_{2-3} .
- 4 A duct-friction term allowing for the 39-in. length of duct

from the core discharge section to the downstream location of the pressure taps, and the 2-in. length of duct upstream of the core, ΔP_{duct} .

These components are related as follows

$$\Delta P = \Delta P_{0-1} + \Delta P_{\text{core}} - \Delta P_{2-3} + \Delta P_{\text{duct}} \dots [5]$$

The entrance pressure drop can be expressed, from reference (7), as

$$\Delta P_{0-1} = K_e \frac{G^2}{2g\rho_1} + \frac{G^2}{2g\rho_1} (1 - \sigma^2) \dots [6]$$

The pressure recovery at the core exit is evaluated in a similar manner.

$$\Delta P_{2-3} = -K_e \frac{G^2}{2g\rho_2} + \frac{G^2}{2g\rho_2} (1 - \sigma^2) \dots [7]$$

The entrance and exit-loss coefficients, K_e and K_a , are evaluated as a function of N_R and the flow-area contraction ratio, using the results of analysis and experiment described in reference (7). The sum ($K_e + K_a$) is considered to be accurate to ± 10 per cent.

The small duct loss, neglecting changes in density, is evaluated as follows, using a nominal magnitude of f_d

$$\Delta P_{\text{duct}} = 4 \left(f_d \frac{L}{D_d} \right) \sigma^2 \frac{G^2}{2g\rho_2} \dots [8]$$

The core pressure drop, which includes the desired friction factor, is evaluated by integration of the differential form of the dynamic equation for flow in a tube

$$\Delta P_{\text{core}} = \frac{G^2}{2g} v_1 \left[2 \left(\frac{v_2}{v_1} - 1 \right) + \frac{f}{r_h} \frac{1}{v_1} v_m L \right] \dots [9]$$

where

$$v_m = \frac{1}{L} \int_0^L v dx$$

Term v_m can be evaluated if v is known as a function of length. This integration is accomplished by using an arithmetic-average pressure, since the pressure drop is relatively small, and the temperature variation indicated by Equation [1]. The resulting equation for v_m is

$$v_m = \frac{2}{(T_1\rho_1 + T_2\rho_2)} \left[T_s - \frac{(T_2 - T_1)}{NTU} \right] \dots [10]$$

Equations [6], [7], [8], and [9] are then substituted in Equation [5] and solved for the friction factor, f .

Reynolds-Number Evaluation. A question arises as to the correct value of viscosity to use for the Reynolds number ($Ar_h G/\mu$), because the temperature, and thus the viscosity, varies with flow length and over the cross section. This problem has been partially resolved by testing for the friction factors both during the heat-transfer tests and by separate isothermal tests. In the latter case there is no question as to the correct viscosity. For the heating tests, a good correlation for turbulent flow is obtained by assuming a film average viscosity based on a temperature halfway between the wall and the arithmetic average of the air temperatures. A more rational procedure might be to use the arithmetic average of wall and logarithmic-average air temperatures, but for these tests the difference is negligible. Both the heat-transfer and friction results are then presented as a function of the "film" average Reynolds number.

ACCURACY AND ERRORS

No attempt is made to analyze rigorously for all possible

sources of error, but rather to estimate the magnitude of the more important ones and use these for arriving at an over-all estimate of the accuracy of the $N_{St} N_{Pr}^{1/3}$ and f versus N_R characteristics. The errors considered are as follows:

- (a) Errors inherent in the design and performance of the test system.
- (b) Instrument inaccuracies.
- (c) Errors introduced by virtue of the idealizations and auxiliary data used in the analysis.
- (d) Uncertainties in the determination of the test-core dimensions.

Air-Flow Metering. The air-orifice installation is made rigorously in accordance with the specifications of reference (3). Using the methods of this reference, the estimated probable error in air-flow metering is ± 0.7 per cent. The fact that no discontinuity in the test results is noted when orifices are overlapped further justifies the assumption of this small probable error, especially since the friction factor varies inversely as the square of the air-flow rate and is thus particularly sensitive to this error.

Heat-Transfer Results. It is believed that the measurements of the critical dimensions of the test cores can be made to ± 1 per cent. The maximum temperature-measurement error, is introduced in the determination of the core downstream temperature. Although the point temperatures are believed accurate to ± 0.2 F, it is probable that because of variations in temperature over the cross section of 2-4 F, Fig. 12, the 27-point traverse yields bulk average temperature results to within only ± 0.5 F. The estimated steam-side resistance is an approximation and is probably only accurate to ± 50 per cent. It should be noted, Equation [2], that the Stanton-number determination is virtually independent of the air-flow rate. A miscellaneous error of ± 1 per cent in Stanton number includes the effect of nonuniform core-entrance air velocity. According to reference (6), Prandtl number is subject to an uncertainty of ± 5 per cent, due primarily to the uncertainty for k for air.

In summary, Table 1 gives a typical estimation of uncertainties in the heat-transfer test results leading to $N_{St} N_{Pr}^{1/3}$

TABLE 1 POSSIBLE ERRORS IN HEAT-TRANSFER TEST RESULTS

	Per cent error at—	
	$N_R = 1000$	$N_R = 10000$
Temperature and dimension measurements.....	± 2.7	± 2.1
Steam-side resistance estimate.....	± 0.6	± 2.5
Miscellaneous.....	± 1.0	± 1.0
Stanton number.....	± 3.0	± 3.4
Prandtl number.....	± 5.0	± 5.0
$N_{St} N_{Pr}^{1/3}$	± 4.5	± 4.8

Friction Factors. The accuracy of the friction factors will depend to a certain extent upon the relative importance of the entrance and exit losses in the various test cores. With the pressure drop measured to ± 0.5 per cent, a ± 1 per cent probable error in the core dimensions, a ± 0.7 per cent probable error in the air-flow rate, and ($K_e + K_a$) accurate to ± 10 per cent, the probable error for a typical test core is ± 5 per cent.

Reynolds Numbers. A ± 1.0 per cent error in the test-core dimensions, a ± 0.7 per cent error in the flow rate, and a further ± 1 per cent error in the air viscosity (from reference 6), indicate a probable uncertainty of ± 1.6 per cent in the Reynolds number determination. The temperature upon which the viscosity is based is a question of interpretation of results and not of experimental accuracy.

tus, test results for a typical louvered-plate-fin heat-exchanger surface are included here. The dimensions of the surface are shown in Fig. 15. Table 2 gives the complete test data for a series of runs covering a Reynolds number range, 400–8000, the practical range of interest for this surface. The $N_{St}N_{Fr}^{2/3}$ given here does not include the allowance for steam-side resistance. It does, however, include the effect of the temperature effectiveness of the fins, see Equation [4]. Table 3 gives the results for the isothermal friction-factor tests. The data of Tables 2 and 3 are plotted in Fig. 15. The recommended friction-factor curve is

drawn through the isothermal data. The recommended heat-transfer curve results from the correction for steam-side resistance. It should be noted that there is very little scattering of test points and that a very good correlation between hot- and cold-core friction factors is obtained. The overlapping of the flowmeters is evident by the closer spacing of the data points in the regions, $N_R = 2000$ and 4000 – 5000 . The energy balances, Table 2, are seen to be mostly on the positive side which is to be expected since 100 per cent separation of the condensate from the blow steam is not possible and thus some condensate is not

metered, making $Q_{\text{sum}} < Q_{\text{air}}$. The negative unbalance at low Reynolds numbers (i.e., high NTU) is due to minor deficiencies in the steam and condensate system, since errors of this magnitude in the temperature measurements would give ridiculous $N_{St}N_{Pr}^{2/3}$ results. Introduction of a separator between the desuperheater water inlet and the core has eliminated this difficulty in later tests.

This test core was tested previously at the U.S.N. Engineering Experiment Station, Annapolis, Md., using a very similar technique to that described here, reference (1), and at the Harrison Radiator Division, General Motors Corporation, using hot water instead of condensing steam on the hot side. Fig. 16 shows a comparison of these various data. The Stanford results are seen to agree closely with those of USNEES, the difference in friction factors being due to the use of different entrance and exit coefficients. USNEES did not allow for steam-side resistance. If they had, their results would run 0-4 per cent higher than shown for N_R 3000-10,000. The maximum spread between all curves is less than 10 per cent.

SUMMARY AND CONCLUSIONS

A test apparatus and technique have been described which will yield accurate heat-transfer and flow-friction data for compact heat-exchanger surfaces. Such data may be used for preliminary design of gas-turbine regenerators and intercoolers, aircraft heat exchangers, and many other types of systems where optimum selection of surfaces will pay a premium in performance, weight, and shape. These data are not only useful for design purposes, but will be used also for a study of the basic phenomena involved in convection heat transfer and flow friction in complex flow passages. Such studies may lead to improved heat-exchanger surfaces.

The experience in the design and operation of this system has indicated that accurate results are obtainable only if the following points are given special attention:

- A method must be provided for controlling the air flow to a uniform velocity distribution at the entrance to the test core.
- Air temperatures must be measured at a large number of points over the flow cross section on the downstream side of the test core. This is preferable to using a single reading of some sort of an average temperature, obtained by flow-mixing methods or averaging types of thermometric primary elements. These

FIG. 16 COMPARISON OF TEST RESULTS WITH DATA OF OTHER INVESTIGATORS

latter methods do not allow a check on one of the basic idealizations of the analysis, namely, that of uniform outlet temperature.

(c) All air-temperature measuring devices must have radiation shields, and the duct walls must be insulated to avoid radiation errors.

(d) Small temperature-measurement inaccuracies will result in excessive error in the heat-transfer results unless the test cores are designed to operate in the limited range of NTU , 0.2-3.0.

(f) Provision must be made for the accurate control of steam pressure and steam-inlet state. A water-injection desuperheater is satisfactory if care is taken to insure essentially complete elimination of the liquid phase before entry into the core.

(g) Care must be taken to locate the air-pressure taps on the downstream side of the test core at a point allowing the maximum pressure recovery. This may amount to 20-30 in. from the core.

(h) The accuracy of the friction-factor tests should be considered in the light of the effect of entrance and exit-flow losses. Because of the limitations on NTU , the extraction of accurate f characteristics from the measurement of core pressure drop requires accurate exit and entrance-flow-loss coefficients. The generally used published data are adequate only for $N_R > 10,000$, reference (7).

(i) A continuous check on the temperature and flow instruments should be provided in the testing procedure, as by direct calibration and energy-balance comparisons.

The experience presented here may be used as a basis for establishing a standard test code for work of this character. Such standardization will have the ultimate advantage of raising the level of the accuracy of basic design data so urgently needed for new applications of existing surfaces or the development of new surfaces.

ACKNOWLEDGMENTS

The Office of Naval Research, the U.S.N. Bureau of Ships, and the U.S.N. Bureau of Aeronautics are currently sponsoring a heat-transfer research program for compact surfaces at Stanford University. The authors prepared this paper on this program and express their appreciation to the sponsoring organizations.

The U.S.N. Engineering Experiment Station, Mr. John Dinan, and Mr. A. E. Senner, have contributed materially to the development of the system described here by keeping the authors

Heat-Transfer and Flow-Friction Characteristics of Some Compact Heat-Exchanger Surfaces

Part 2—Design Data for Thirteen Surfaces

New developments in prime-mover and process equipment have created a greater need for compact heat-transfer surfaces. This paper presents basic heat-transfer and flow-friction design data for thirteen such surfaces which may be described generally as the plate-fin type and finned-flat-tube type. In addition to the use of the conventional nondimensional correlations, the various surfaces are compared on heat-transfer coefficient versus flow-friction-horsepower basis. Paper No. 49—A-95.

NOMENCLATURE

The following nomenclature is used in this paper:

English Letter Symbols:

- A = transfer area, ft^2
- A_s = free-flow area, ft^2
- A_{fr} = frontal area, ft^2
- a = plate thickness for the plate-fin surface, ft
- b = plate spacing, in. , ft
- c_p = specific heat at constant pressure, $\text{Btu}/(\text{lb } ^\circ\text{F})$
- E_{std} = friction power evaluated at certain standard gas properties (see caption Fig. 9), $\text{hp}/(\text{ft}^3 \text{ of } A)$
- f = Fanning friction factor, dimensionless
- G = mass velocity based on A_s , $\text{lb}/(\text{hr ft}^2 \text{ of } A_s)$
- h = unit conductance for thermal convection heat transfer, $\text{Btu}/(\text{hr ft}^2 ^\circ\text{F})$
- h_{std} = unit conductance evaluated at certain standard gas properties (see caption Fig. 9), $\text{Btu}/(\text{hr ft}^2 ^\circ\text{F})$
- K_c = contraction loss coefficient for air flow at test-core entrance, dimensionless
- K_e = expansion-loss coefficient for air flow at test-core exit, dimensionless
- k = thermal conductivity, $\text{Btu}/(\text{hr ft}^2 ^\circ\text{F}/\text{ft})$
- L = exchanger or test-core flow length, ft , in.
- l = louver spacing, ft , in.
- r_H = flow passage hydraulic radius based on free-flow area, A_s (see Equation (1)), ft
- V = exchanger total volume, ft^3

Greek Letter Symbols:

- α = ratio of total transfer area of one side of exchanger to total volume of exchanger, ft^2/ft^3
- β = ratio of total transfer area of one side of exchanger to volume between plates of that side, ft^2/ft^3
- ρ = gas density, lb/ft^3
- σ = ratio of free flow to frontal area, dimensionless
- μ = gas viscosity, evaluated at bulk average temperature, $\text{lb}/(\text{hr ft})$
- μ_f = gas viscosity, evaluated at film average temperature, $\text{lb}/(\text{hr ft})$

Dimensionless Groupings:

- N_{St} = Stanton's number, (h/Gc_p) , a heat-transfer modulus

- N_{Pr} = Prandtl's number, $(\mu_f c_p/k)$, a fluid-properties modulus evaluated at film average temperature
- $N_{St} N_{Pr}^{1/3}$ = generalized heat-transfer grouping; this factor versus N_R defines heat-transfer characteristics of surface
- NTU = number of heat-transfer units for an exchanger
- N_R = Reynolds number, $(4r_H G/\mu)$, a flow modulus characterizing type of flow
- N_{Rf} = $(4r_H G/\mu_f)$, a tube-type-flow Reynolds number
- N_{Rl} = (lG/μ) , a flat-plate-type-flow Reynolds number
- f = Fanning friction factor based on r_H ; $f - N_R$ plot defines friction characteristics of surface

INTRODUCTION

The advent of the gas turbine as a promising transportation-type prime mover, the development of portable oxygen plants, and the continued emphasis on reduced size and weight in aircraft installations have served as strong stimuli to the development and application of lightweight compact heat-transfer surfaces.

As a matter of definition, the term compactness refers to the transfer area-to-volume ratio characteristic of the surface in question. A compact surface, for the purposes of this paper, is one providing more than 75 sq ft of transfer area per cu ft of core volume. This compares to the approximately 20 ft^2/ft^3 which can be realized at best from 1-in.-diam tubes in a shell-and-tube-type construction.

For many heat-exchanger applications, particularly those employing liquids, an accurate knowledge is not required for the friction characteristics of the surface. However, for low-density fluids such as gases, the cost of friction per unit of mass flow is greatly multiplied, and the frictional characteristics of the surface are of equal significance as the heat-transfer behavior. The flow-friction consideration is particularly important for gas-turbine-plant heat exchangers—the regenerator and the intercooler.

The purpose of this paper is to present basic heat-transfer and flow-friction design data for thirteen compact surfaces. These surfaces may prove to be useful in the gas-turbine and other applications where careful design will pay a premium in compactness and performance. Heretofore new applications have been inhibited by the lack of availability of such data.

DESCRIPTION OF SURFACES

In part, the data presented here supplement the information given in reference (1).¹ This reference reports the characteristics of seven variations of a plate-fin type of extended surface which has been extensively used in the supercharged aircraft-engine intercooler application. The general features of this surface are described in Fig. 1, which also shows the eight plate-fin surfaces considered in this paper. The scheme of designating the different surfaces in this illustration may be inferred from the following ex-

¹ Numbers in parentheses refer to the Bibliography at the end of the paper.

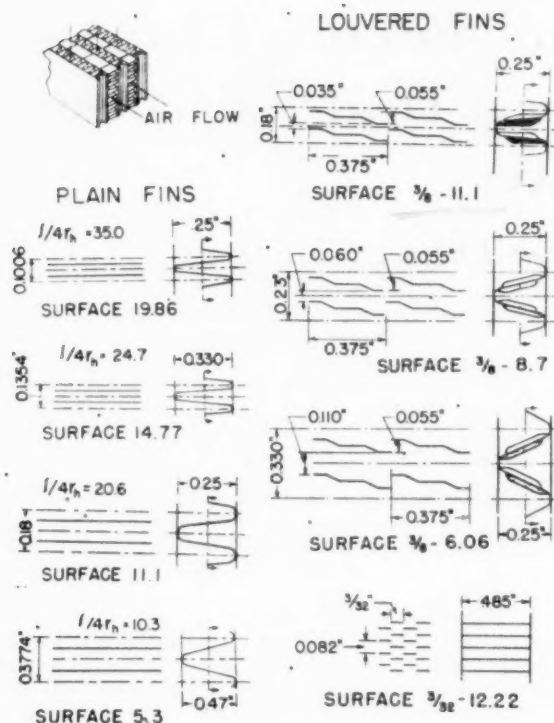

FIG. 1 DESCRIPTION OF PLATE-FIN-TYPE SURFACES
(See Tables 1 and 3 for further geometrical data.)

planation for the $3/8$ -8.7 surface. This surface has 8.7 fins per in. and the fin louvers are spaced $3/8$ in.

Two of these variations—designated as plain fins 11.1 and louvered fins $3/8$ -11.1—were reported previously (1). They were retested and their characteristics reported here for comparative purposes.

Four of the eight plate-fin surfaces described in Fig. 1 provide a systematic variation of fin spacing for the plain-fin type as indicated in Table 1. The surface designated $3/8$ -12.22, Fig. 1, Table 1, is representative of the plate-louvered-fin type with a very short fin-flow length. Although the so-called plain-fin surface cores were designed for the study of the characteristics of an uninterrupted fin, manufacturing methods required that the fin material be cut in 2.5-in. strips. Consequently, these surfaces may be considered as a louvered surface with a louver spacing of 2.5 in.

LOUVERED FINS

FIG. 2 DESCRIPTION OF FIN-FLAT-TUBE-TYPE SURFACES
(See Table 1 for further geometrical data.)

Fig. 2 and Table 1 describe five fin-flat-tube-type surfaces useful for gas-to-liquid heat transfer such as the automobile radiator, or the water-cooled intercooler of a gas-turbine plant, or a gas-turbine regenerator if a suitable intermediate heat-transfer fluid, such as a liquid metal, can be developed.

The surface designated 11.37-.737-S-R has 11.37 fins per in., flat tubes 0.737 in. wide, the tubes are staggered (S) and the fins are ruffled (R). The significance of the other designations may be inferred from the foregoing. The five variations considered here allow a study of the effects of staggered versus in-line tubes, ruffled versus plain fins, and staggered tubes combined with ruffled fins versus in-line tubes and plain fins. Also, the comparisons of 9.29-.737-S-R and 11.32-.737-S-R at least suggest the influence of fin spacing on a staggered-tube and ruffled-fin design.

Table 1, together with the description of Figs. 1 and 2, provides all the detailed geometrical information required for applications to heat-exchanger design. For all of these surfaces the hydraulic radius is defined relative to the flow dimension L , as

$$\frac{r_H}{L} = \frac{A_c}{A} \quad [1]$$

For cylindrical tubes of any cross-section geometry, i.e., the plate-fin surface, this definition reduces to the conventional result, r_H equals the flow cross section divided by the wetted perimeter.

TABLE 1 GEOMETRY OF THE DIFFERENT SURFACES

Surface designation	Fins per in.	Hydraulic radius, r_H , ft	Plate spacing, in.	Tube or fin thickness, in.	Extended Total area	Area (Volume between plates) δ , ft ² /ft ²	Area Core volume α , ft ³ /ft ²	Free flow Frontal area σ

$3/8$ -12.22	12.22	0.002941	0.485	0.004	0.862	302		
Fin-flat-tube type:								
9.68-0.870	9.68	0.00295		0.004	0.795		229	0.697
9.68-0.870-R	9.68	0.00295		0.004	0.795		229	0.697
9.1-0.737-S	9.10	0.00345		0.004	0.813		224	0.785
9.29-0.737-S-R	9.29	0.00338		0.004	0.814		226	0.788
11.32-0.737-S-R	11.32	0.00288		0.004	0.845		270	0.780

For other surfaces, however, where flow cross-section area and perimeter are variable along the flow dimension, as, for instance, the finned-flat-tube type, the definition Equation [1] is necessary.

This definition is more readily usable in heat-exchanger design. As an illustration, the nondimensional exchanger size factor directly relating to the exchanger heat-transfer effectiveness (2), is the "number of heat-transfer units"

$$NTU = \frac{U}{Gc_p} \frac{A}{A_s} = \frac{U}{Gc_p} \frac{L}{r_H}$$

where the flow mass velocity G is based on the minimum flow cross section, A_s . The Gc_pA_s product has the significance of flow stream-capacity rate.

To facilitate extension of the test results reported here to heat-exchanger-design calculations, the interrelations of the surface and the core geometrical factors are summarized. The heat-exchanger core consists of two surfaces—one for each fluid side—except for the case of the periodic-flow-type exchanger, such as the common Ljungström air preheater.

1 The following geometrical factors are given in Table 1 for each surface reported here as part of the basic data

b , r_H , and β for the plate-fin type

r_H , α , and σ for the fin-flat-tube type

2 The solution for a particular heat-exchanger core requires the following factors for each of the two sides

A , A_c , A_{fc} , L , and σ

For the complete core, V and α are also required. In the case of the plate-fin surface, the plate thickness (a , ft) between the two sides must be specified as an independent variable.

3 The foregoing surface and core factors are related as follows for one side of the exchanger: Subscript 1 refers to any one side and 2 to the other side. Factors without subscripts are common to both sides.

$$\left. \begin{aligned} \sigma_1 &= \left(\frac{A_c}{A_{fc}} \right)_1 = \left(\frac{Ar_H}{A_{fc}L} \right)_1 = \frac{(Ar_H)_1}{V} \\ \sigma_1 &= \frac{b_1\beta_1r_H}{b_1 + b_2 + 2a} \text{ (plate-fin surface only)} \end{aligned} \right\} \dots [2]$$

$$\left. \begin{aligned} \alpha_1 &= \frac{A_1}{V} = \left(\frac{A}{A_{fc}L} \right)_1 = \left(\frac{\sigma}{r_H} \right)_1 \\ \alpha_1 &= \frac{b_1\beta_1}{b_1 + b_2 + 2a} \text{ (plate-fin surface only)} \end{aligned} \right\} \dots [3]$$

$$A_{c1} = (\sigma A_{fc})_1 = \left(\frac{Ar_H}{L} \right)_1 = \left(\frac{A\sigma}{L\alpha} \right)_1 \dots [4]$$

$$\left(\frac{r_H}{L} \right)_1 = \left(\frac{A_c}{A} \right)_1 = \left(\frac{\sigma}{L\alpha} \right)_1 \dots [5]$$

The same relations of course apply to side 2 with an exchange of subscripts 1 for 2 and 2 for 1.

EXPERIMENTAL METHOD AND ACCURACY OF RESULTS

The test arrangement, method of analyzing the data, and a consideration of errors are covered in considerable detail in reference (3). Consequently, only a brief summary will be presented here for the sake of completeness.

The test system provided for condensing steam to air heat transfer with air flow on the surface of interest. The direct test data allowed determination of the over-all heat-transfer coefficient

steam to air, and the air-side-core pressure drop. The test-core dimensions were all of approximately $8\frac{3}{4} \times 9\frac{3}{4}$ in. frontal area and 5 in. in the flow length on the air side.

Allowance for the ineffectiveness of the extended surface and the steam-side condensate-film resistance permitted the evaluation of the average unit conductance for thermal convection on the air side. The friction factor was extracted from the core-pressure-drop data by allowing for entrance and exit flow-stream mechanical-energy losses (4), and for flow acceleration accompanying density changes due to both pressure and temperature variations along the flow length. Friction factors were determined from isothermal tests and also for runs with core heating.

Fig. 5 for the plate-louvered-fin surface $\beta_{12}/22$ is typical of the consistency of the test results for all the surfaces tested. The recommended friction-factor curve is based upon the data for the isothermal runs. The recommended heat-transfer factor $(h/Gc_p)N_{Pr}^{1/4}$ versus N_{Re} curve falls above the test points. The difference represents the allowance for steam-side resistance. The method used here was to fair a curve through the data points shown, and then evaluate the steam-side resistance for several test Reynolds numbers over the range to determine the correction to the faired curve to obtain the recommended curve.

The test data allowed energy balances to be made, and the average deviation for the series of tests applying to any one surface was usually less than 3 per cent. The one exception was for the low-Reynolds-number runs for the 5.3 plain-fin surface where, due to faulty operation of the condensate weighing system, poor balances were obtained. However, the air-side data used in the calculations of results are believed to be accurate. An analysis of errors similar in detail to that given in reference (3), indicates that the probable errors for the basic results presented here are less than the following indicated magnitudes:

$$\begin{aligned} N_{Re} &\pm 2 \text{ per cent} & f &\pm 7 \text{ per cent for plain-plate-fin type} \\ N_{St} &\pm 3.5 \text{ per cent} & f &\pm 5 \text{ per cent for louvered-plate-fin type} \\ N_{Pr} &\pm 5 \text{ per cent} & f &\pm 2 \text{ per cent for finned-flat-tube type} \\ N_{St}N_{Pr}^{1/4} &\pm 5 \text{ per cent} \end{aligned}$$

The difference in the estimated errors for the friction factors reflects the relative contribution of the entrance and exit flow losses to the over-all pressure drop. The properties of air—viscosity μ and N_{Pr} —used in generalizing the test results to a non-dimensional form were obtained from reference (5).

BASIC HEAT-TRANSFER AND FLOW-FRICTION DESIGN DATA

The heat-transfer and flow-friction characteristics of the various surfaces are presented as follows:

1 Figs. 3, 4, and 5 give the nondimensional correlation of friction factor f , and heat-transfer modulus, $N_{St}N_{Pr}^{1/4}$, versus Reynolds number, N_{Re} , for the eight variations of the plate-fin type of surface. Fig. 6 gives the same correlations for the finned-flat-tube type. In every case here the Reynolds number is based on the flow hydraulic-diameter dimension defined by Equation [1].

2 In contrast to the foregoing comparison, Figs. 7 and 8 present the correlations employing a Reynolds number, N_{Re} , based upon an uninterrupted flow length, or louver spacing, for the eight plate-fin surfaces.

3 Fig. 9 compares the plate-fin surfaces on a heat-transfer versus friction-power basis (1). However, unlike reference (1), the basis selected, instead of being per unit transfer area, is per unit of volume between plates, $(h_{ad}\beta)$ versus $(E_{ad}\beta)$. The gas properties used as a reference in this comparison correspond to air at 1 atm pressure and 500 F. These properties are given in

(Nondimensional heat-transfer and friction characteristics on a tube-type N_R basis; data points illustrate the typical consistency of test results; see Fig. 1, and Tables 1 and 3 for geometrical data.)

the caption of Fig. 9. Equations [6] give the extrapolation for fluid properties differing from the reference conditions.

4 Fig. 10 gives a similar comparison for the finned-flat-tube-type surfaces. Here, however, the total core volume rather than volume on one side only is used, $(h_{td}\alpha)$ versus $(E_{td}\alpha)$.

5 The co-ordinates $N_{St}N_{Pr}^{1/3}$ and f versus N_{Rf} of the recommended curves are summarized in tabular form, Table 2, for all surfaces.

To avoid confusion, test-data points are given only for the 3_{32} -12.22 louvered-plate-fin surface. The test data for the approximately 30 heat-transfer and 30 isothermal runs per surface are available elsewhere (6, 7, 8, 9).

DISCUSSION AND COMPARISON OF SURFACES

Plain-Plate-Fin Surfaces, Fig. 1. The illustrations in Fig. 1 describe the roughly triangular-tube flow cross sections common to all of these surfaces. Therefore, as for the case of circular-tube flow, it may well be that a single correlation for heat-transfer and

FIG. 4 LOUVERED-PLATE-FIN SURFACES WITH $3/8$ -IN. LOUVER SPACINGS

FIG. 6 FIN-FLAT-TUBE SURFACES

(Nondimensional heat-transfer and friction characteristics compared on a tube type N_R basis. Comparable characteristics of 19.86 plain-fin surface are also shown; see Fig. 2, and Table 1 for geometrical data.)

another for friction characteristics would apply for a range of plate and fin spacings. The data in Fig. 3 are not completely conclusive in this respect for the following reasons:

1 Manufacturing methods required that the test cores be constructed with a fin sheet material only 2.5 in. in flow length, resulting in the varying $l/4r_h$ magnitudes summarized in Table 3, ranging from only 10.3 for the 5.3 fins per in. surface to 35 for the 19.86 fins per in. surface.

2 Each of the four test cores had a total air-flow length of only 5 in. The effect of abrupt flow contraction at the entrance to the core will partially influence the heat-transfer and friction characteristics some distance downstream. Only for the 19.86 surface, with a core-air-flow length of 70 hydraulic diam, is this dimension considered to be great enough to yield data accurately descriptive of the long flow lengths that will be encountered in applications.

3 The aluminum furnace brazing technique of core construction produced filleted corners and a somewhat roughened surface.

Fig. 3, which brings out the similarities to tubelike flow, employs a Reynolds-number abscissa based on the flow hydraulic diameter. In contrast, Fig. 7, using an N_R based on the fin flow-length dimension l , emphasizes the similarities to flow over a flat plate.

The results, with the exception of those for the 5.3 surface for heat transfer, correlate quite well on a tube-type Reynolds-number basis (within 12 per cent for heat transfer and 18 per cent for friction). A transition from laminar to turbulent flow in the approximate range $1200 < N_{Rf} < 2500$ is common to all four surfaces.

The foregoing considerations suggest that the f and $N_{St}N_{Pr}^{2/3}$ versus N_{Rf} characteristics of the 19.86 surface are the best single set of correlations to use for a variety of fin and plate spacings within the follow restrictions: (a) Fin spacing 7–25 fins per in.; (b) $l/4r_H > 25$; (c) plate-to-fin spacing 2.5–5; (d) the core flow length to hydraulic diameter greater than 50.

In distinction to the previous tube-flow-basis comparison, consider Fig. 7 which emphasizes the similarities to flat-plate flow. The flat-plate heat-transfer characteristics were derived from the friction-factor behavior using the friction-heat transfer analogy

$$N_{St}N_{Pr}^{2/3} \cong f/2$$

With respect to heat transfer, only in the fully developed turbulent-boundary-layer flow, $N_{Rf} > 50,000$, does close similarity exist between the four surfaces and the flat-plate characteristic. Unlike the tube-flow comparison in Fig. 3, the different surfaces exhibit transition flow at differing Reynolds numbers, N_{Rf} , and do not correlate at all with each other in the laminar-boundary-layer-flow regions.

The excellent agreement of the 5.3 surface behavior with that of the flat-plate-flow system, especially with respect to heat transfer, is significant. Evidently, because of the wide fin spacing and small $l/4r_H$, a fin has a relatively minor effect on the flow over a neighboring fin with the resulting similarity to flat-plate flow.

The foregoing discussion is of restricted generality because of various factors not under experimental control, primarily the uninterrupted flow length l , and the surface roughness. A more complete understanding of the behavior of these surfaces will require the testing of additional cores of a fixed $l/4r_H$ on the order of magnitude of 35 to 50.

Lowered-Plate-Fin Surface* Fig. 1. The average thickness of the laminar sublayer is reduced by interrupting the fin surface with louvers (1). Consequently, the resistance to thermal convection heat transfer is decreased and the film coefficient h , in-

creased. While the friction factor f is also made larger by this expedient, it is often possible to operate with a smaller friction power expenditure as compared to the plain-fin surface, since lower flow velocities may be used.

The interpretation of the behavior of the louvered surfaces in terms of tubelike and flat-plate-like behavior is not as valid as in the case of the plain-fin surfaces because of the more complex flow geometry. For the three $3/8$ -in. louvered surfaces, described in Fig. 1, the curvature of the fins produces minus accelerations with resulting tendencies toward flow separation and eddy formation. For all four louvered surfaces, wake effects at the leading and trailing edges and flow impingement on the blunt leading edges provide additional flow turbulence. The prime surface, accounting for 14 to 38 per cent of the total, Table I, has a markedly different geometry from the louvered fins. The junctions, louver-to-fin and fin-to-plate, introduce more flow complexities. Nevertheless, the tube-type-flow and flat-plate-type-flow comparisons employed for the plain-fin surfaces yield usable correlations, Figs. 4, 5, and 8.

The sequence of three $3/8$ -in. louvered surfaces have their characteristics presented on a tube-type N_R basis, Fig. 4. The close correlation of the heat-transfer behavior suggests that any one of these curves may be used with good accuracy for a range of fin spacings from 5 to 15 fins per in., maintaining the $3/8$ -in. louver spacing. Note that all three surfaces exhibit a flow transition in the range $1500 < N_{Rf} < 3000$ as for the case of the plain-fin surfaces.

No satisfactory explanation has been evolved to explain the poorer friction correlation, especially for $N_{Rf} > 2000$, Fig. 4. In terms of the contribution of the unlouvered prime surface one would expect a less rough-flow characteristic for the $3/8$ –6.06 surface as compared to the $3/8$ –11.1 surface, Fig. 1. This is not supported by the test results which show a higher f for 6.06-fins-per-in. surface especially for the higher N_{Rf} range. Possibly the closer fin spacing reduces flow-separation effect thereby reducing the form drag component of the friction factor without a material alteration of the heat transfer, which is associated with the skin-friction component. An additional possibility is that the closer fin spacing serves to reduce the scale and intensity of the turbulent eddies, much in the manner of a fine screen.

Until more complete data are available, it is recommended that the three f characteristics in Fig. 4 be used for interpolation and possibly a small extrapolation to other fin pitches in the range 5 to 15 fins per in.

The characteristics of the short-louvered surface $3/32$ –12.22 are given on a tube-flow Reynolds number basis, Fig. 5. No discernible flow transition appears in either the f or $N_{St}N_{Pr}^{2/3}$ characteristic. Comparison with Fig. 4 reveals that the $3/32$ –12.22

surface, as compared to the $3/8$ -11.1 surface, has a 12 to 25 per cent higher heat-transfer characteristic and 50 per cent higher f characteristic.

Fig. 8 contrasts behavior of the $3/32$ -12.22, the $3/8$ -11.1, and the 11.1 plain-fin surfaces on a flat-plate-type basis, with the louver dimension, as given in Table 3, entering into the Reynolds number, N_R . Considering the marked lack of geometrical similarity between the flat plate and the three test surfaces, the

TABLE 3 COMPARISON OF PLATE-FIN SURFACES

Designation	No. of fins per in.	Hyd. diam. $4r_H$, in.	Louver spacing, l , in.	$l/4r_H$
Plain:				
5.3	5.3	0.2419	2.5	10.3
11.1	11.1	0.1214	2.5	20.6
14.77	14.77	0.1017	2.5	24.7
19.86	19.86	0.0718	2.5	35.0
Louvered:				
$3/8$ -6.06	6.06	0.1752	0.375	2.14
$3/8$ -8.7	8.7	0.1436	0.375	2.61
$3/8$ -11.1	11.1	0.1214	0.375	3.08
$3/32$ -12.22	12.22	0.1411	0.0937	0.663

agreement with respect to heat transfer is remarkably good. This has been observed by others, notably by Norris and Spofford in their pioneer work on "high-performance fins" (10). The friction characteristics for the test surfaces, however, are only in very general agreement with each other and are substantially higher than the flat-plate characteristics. For the $3/32$ -12.22 and $3/8$ -11.1 surfaces, f is roughly twice that for the flat plate with the sharp leading edge, demonstrating that about one half the friction power expenditure is a form drag effect, not contributing to heat transfer. In spite of the higher parasitic loss, the louvered surfaces still yield a higher h , for a given friction power expenditure, E hp/ft, as compared to the plain-fin surfaces, because of the higher $N_{St}N_{Pr}^{1/3}$ characteristic. This aspect will be elaborated on shortly.

Finned-Flat-Tube Surfaces, Fig. 2. The characteristics of these surfaces are summarized in Fig. 6, using a tube-type-Reynolds number. The dotted curves give the behavior of the 19.86 plain-plate-fin surface for comparative purposes.

The close agreement of the 19.86 plain-fin and the 9.68-.87 finned tube surface emphasizes their common tubelike flow behavior. The agreement with respect to heat transfer is remarkably good, the spread being less than 5 per cent. For friction, the spread in f is not more than 25 per cent at the higher N_{Rf} range, and much less for $N_{Rf} < 1000$.

The effect of staggering the tubes but maintaining the plain-fin surfaces is striking. This is revealed by the comparison of the 9.68-.87 and 9.1-.737-S surfaces, Fig. 6. For the whole Reynolds-number range, there is an increase of N_{St} of from 15 to 50 per cent and a roughly proportional increase of f . Maintaining an in-line tube arrangement but ruffling the fins, surface 9.68-.87-R versus 9.68-.87 (see Fig. 2), produces like increases in N_{St} and f , but relative to the staggered-tube plain-fin geometry the improvement in N_{St} is less, and, in general, the friction is higher. Consequently, from a friction-heat transfer point of view, staggering alone is more advantageous than ruffling alone. In these comparisons the small difference in single-tube dimensions and the variations in fin spacing are not considered as significant.

The influence of both staggering the tubes and ruffling the fins over those expedients carried out singly can be determined by the comparison of the characteristics for surfaces 9.68-.87, 9.68-.87-R, 9.1-.737-S, and 9.29-.737-S-R. For a $N_{Rf} > 4000$, for heat transfer, the effects of staggering and ruffling are almost directly additive, giving about a 50 per cent increase in N_{St} over the in-line-tubes plain-fin arrangement. The friction curve is also higher than either the staggered or ruffled arrangement, being of the same shape as the ruffled arrangement

but 15-30 per cent higher over the whole Reynolds number range. For $N_{Rf} < 2000$ there is no significant gain of the S-R over the staggered arrangement with respect to heat transfer, and a decided loss with respect to friction.

The only significant change of fin spacing exists for the comparison 9.29-.737-S-R versus 11.32-.737-S-R, where there is a 22 per cent increase in fin pitch. The test results demonstrate both a lower friction and a lower heat-transfer performance for the closer fin spacing, on the order of 7-12 per cent over the N_{Rf} range 400 to 10,000. This relatively small difference may not be fundamental, but due, rather, to uncontrolled variations of test-core geometry, such as surface roughness introduced by the solder-dip method of fabrication.

From the point of view of moderate extrapolations to other fin spacings, say, in the range 7-12 fins per in., it is the authors' opinion that the characteristics of the ruffled and/or staggered arrangements, 9.1-.737-S, 9.68-.87-R, and 9.29-.737-S-R, will apply for the respective tube-and-fin surface geometry described in Fig. 2. A precaution to be observed, however, is that changes in the cross-sectional dimensions and spacing of the flat tubes may have a strong influence for the staggered arrangements, and that variations of the ruffled-fin geometry may also be significant for both staggered and in-line tubes.

For the plain-fin in-line-tube types, it is believed that the tube-like flow behavior of the 9.68-.87 surface may be extrapolated over a range 6-20 fins per in. within an uncertainty of ± 10 per cent on heat transfer and ± 20 per cent for friction. This recommendation arises from the agreement in behavior of this surface with the 19.86 plain-plate-fin geometry, Fig. 6.

Heat-Transfer Coefficient Friction-Power Considerations, Figs. 9 and 10. These comparisons are descriptive since, in some measure, they compare the relative sizes of exchangers incorporating the different surfaces. The abscissa is the friction horsepower per unit volume, $E\alpha$ or $E\beta$, hp/ft³, and the ordinate is the heat-transfer power per unit volume and a unit temperature potential, ah or βh , (Btu/hr)/(ft³°F). For a given friction-power expenditure these ordinates are inversely proportional to the relative volume requirements. This method of presentation evolved from the work of references (11), (1), and (12).

For the finned-flat-tube surfaces, the core volume is used as a basis and for the plate-fin surfaces the volume between plates on one side only is employed. This leads to the use of ah versus $E\alpha$, and βh versus $E\beta$ for Figs. 10 and 9, respectively. The reason for this difference in treatment results from the fact that, for the plate-fin surface, the flow geometries on each of the two sides of the core may be selected independently of one another, i.e., $3/8$ -11.1 surface with $1/8$ -in. plate spacing on one side and a plain 19.86-fins per in. surface with $1/8$ -in. plate spacing on the other side. No such freedom exists for the finned-flat-tube type.

The curves; Figs. 9 and 10, were derived for a fixed set of fluid properties corresponding to dry air at 1 atm pressure and 500 F, as given in the captions. These "standard" or reference properties and the resulting h and E magnitudes are designated by the subscript std. For any other fluid properties condition μ , c_p , ρ , N_{Pr} , the co-existing heat-transfer and friction-power coefficients may be evaluated from

$$h = h_{std} \left[\frac{c_p}{c_{p, std}} \right] \left[\frac{\mu}{\mu_{std}} \right] \left[\frac{N_{Pr, std}}{N_{Pr}} \right]^{1/3} \quad (6)$$

$$E = E_{std} \left(\frac{\rho_{std}}{\rho} \right)^2 \left(\frac{\mu}{\mu_{std}} \right)^2$$

This extrapolation is founded on keeping Reynolds number and flow geometry constant.

quite evident from Fig. 9. For instance, for a given friction-power expenditure the $3/8$ -11.1 surface has, roughly, a 45 per cent greater transfer coefficient per unit volume than the 11.1 plain-fin surface. Increasing the transfer area per unit volume by closer fin spacing is also advantageous. The $3/8$ -11.1 surface shows a 45 per cent greater h than the $3/8$ -6.06 surface because of this effect. The expedient of closer fin spacing can be employed instead of louvering to realize high performance as seen by comparing the 19.86 plain fin and the $3/8$ -11.1 surfaces. The latter surface, however, will produce the lighter weight heat exchanger.

It may be that decreasing the louver spacing below $3/8$ to $1/4$ in. is not advantageous as demonstrated by the comparison of $3/32$ -12.22 surface behavior with the better flow friction-heat transfer power characteristic of the $3/8$ -11.1 surface. This point is also suggested by the data of reference (1) in the comparison of louvered-plate-fin surfaces all with 11.1 fins per in. but louver spacings of $3/16$, $1/4$, and $3/8$ in., respectively.

Fig. 10 strikingly illustrates the advantage of staggering the tubes alone over ruffling the fins for the finned-flat-tube surface. Staggering and ruffling together prove advantageous only for the higher $αE_{tot}$ range, corresponding, roughly, to the air side of regenerator or compressor intercooler operation as examples. The improvement of the 11.32-737-S-R over the 9.29-737-S-R surface is due solely to the increased area per unit volume, $α$.

An important point to keep in mind when making these heat-transfer-friction power comparisons is that core "volume" requirement is only one aspect of compactness of the final heat-exchanger design and that "shape" is exceedingly important (2). As a consequence, to realize a satisfactory shape, it may be necessary to employ other than the optimum surfaces as defined in Figs. 9 and 10.

Comparison With Results of Other Experimenters. The plate-fin test cores plain 11.1, $3/8$ -11.1, $3/8$ -8.7, and $3/8$ -6.06 were previously tested at the U.S.N. Engineering Experiment Station, Annapolis, Md. The results for the plain 11.1 and louvered $3/8$ -11.1 surfaces were reported previously (1). The other surfaces are covered in reference (12). The results of the two sets of experiments agree within a maximum of 7 per cent for both heat-transfer and friction for the louvered-fin sequence. For the plain-fin core, while the heat-transfer behavior is in accord, the f results differ by 11-20 per cent. In this core, unlike the others, entrance- and exit-flow losses are substantial, amounting to as much as 30 per cent of the total pressure drop. The USNEES results are higher with respect to both N_{St} and f .

The discrepancies on f can be largely accounted for in terms of the different exit and entrance-flow loss coefficients. The coefficients used by USNEES are the conventional information in the hydraulics literature which apply with reasonable accuracy only to high N_R flow, while the Stanford treatment used test determined coefficients (3) and (4). These comparisons emphasize the importance of having accurate information on these flow factors for work of this character.

The disparity in N_{St} while not so serious, cannot be explained. The fact that the Stanford results include an allowance for steam-side resistance should tend to make them somewhat greater than the EES results for $N_{Rf} > 3000$. This is not the case.

SUMMARY AND CONCLUSIONS

The foregoing discussion leads to the following conclusions:

- 1 The data presented here are of sufficient accuracy for preliminary design calculations for new applications of these surfaces.
- 2 No optimum surface can be specified from these results alone. The designer must select the best surface for a given ap-

plication giving consideration to such factors as cleanability and fouling characteristics, weight, size, and shape.

3 The nondimensional correlation between the variations of a type of surface are sufficiently good so, as to suggest that the results reported here may be interpolated and extrapolated to some extent to other modifications.

4 Plate-fin surfaces exhibit both tubelike and platelike flow characteristics depending to some extent upon the length-to-hydraulic diameter ratio of the surface.

5 In general, the heat-transfer characteristics are more descriptive of the boundary-layer flow than f . The reason for this is the large contribution of form drag effects.

6 Since the form drag effects are largely parasitic, in that they do not contribute to the heat transfer, as more information is accumulated superior surfaces from a heat-transfer-friction power point of view may result.

7 The surfaces reported here with one exception are now being used only for relatively low-temperature applications. Design studies for such high-temperature applications as the gas-turbine regenerator (2), may reveal that an effort should be made on the part of the industry to learn how to fabricate these surfaces for high-temperature service.

ACKNOWLEDGMENTS

The Office of Naval Research, the U.S.N. Bureau of Ships, and the U.S.N. Bureau of Aeronautics are currently sponsoring a heat-transfer research program for compact surfaces at Stanford University. The authors prepared this paper as part of this program and express their appreciation to the sponsoring organizations.

The U.S.N. Engineering Experiment Station, by keeping the authors in close touch with their similar program, has contributed materially to the ideas presented here.

Mr. John Godfrey and Mr. L. P. Saunders of Harrison Radiator, Mr. C. T. Perkins and Mr. Clyde Simpelaar of Modine, Mr. H. C. Rooks of Trane, and Mr. S. K. Andersen of AiResearch, have aided this work by providing test cores of various surfaces and by their suggestions.

Discussion

D. ARONSON.² The work here reported is a valuable addition to our knowledge of convective heat transfer. In the specific application of the performance data to the design of gas-to-gas heat exchangers there are some differences in viewpoints between the authors and the writer, largely as regards which factors deserve prime emphasis. Compactness is a consideration in gas-turbine design but usually is secondary to shape requirements. As a rule the compressor and turbine are first laid out roughly and then, in whatever convenient space can be found, a regenerator is fitted in. The choice to be made is then not of the most compact surface but of one which will give the balance between required NTU and pressure drop which will result in the best gas-turbine cycle.

This condition was vividly demonstrated to the writer when he first attempted to design a cross-flow regenerator for a locomotive gas turbine. At that time his company had on order heat exchangers for an oxygen plant. These exchangers used the $3/32$ -12.22 fin which is shown in Fig. 9 of the paper to be about the most compact pattern. Since space is a most important consideration in a locomotive, this particular surface appeared to offer excellent possibilities. Calculations, however, quickly revealed that such a surface would be entirely unsuitable. Amazingly enough, the 5.3 plain fin, which is indicated as the least compact surface in Fig. 9, proved to be the one which would give the required NTU of about 2 without exceeding the allowable pressure drops. The following is a comparison of the dimensions required for the two cores:

	Length, ft			Volume, cu ft
	Gas flow	Air flow	No flow	
$3/32$ -12.22 fin	$2/4$	$2/4$	80	45
Plain-5.3 fin	3	7	7	147

In terms of actual core volume the compact surface is truly more compact, but if the volume of distributing sections and inlet and outlet manifolds are added, the total volume comes out higher than for the less compact plain-fin pattern. Obviously, the compact surface cannot be used on a locomotive installation.

One can state a general rule for selection of core structures for gas-turbine regenerators. The more compact surfaces are suitable for small air flows and the less compact surfaces for large air flows; also, the more compact surfaces are the better for high values of NTU and the less compact surfaces for low values of NTU . The availability of the test data presented by the authors in this and previous papers is of considerable aid in making the optimum selection. For design work it would have been helpful to have included plots of j/f versus N_{Re} and plots of h versus E , friction power.

For oxygen plants, while compactness is important, a more significant factor is the cost. The authors mention that these surfaces have been used in portable oxygen plants. However, at present many of the companies manufacturing these extended-surface structures are interested in their use in tonnage oxygen plants where heat exchangers represent a significant part of the total cost. The most compact surfaces are probably made with pin fins or wire screening having very fine diameter wires. Such

surfaces would require fairly small passage heights in order to maintain high fin effectiveness.

However, such a design would not necessarily represent the lowest cost. A major part of the cost is in forming the fin elements and assembling them into passages between separating plates. Therefore it is desirable to have as high a passage as possible.

There are many blank spaces remaining to be filled between test-core data and large-scale performance. Future programs might include investigation of such factors as the following:

1 Effect on regenerator performance of complex flow pattern of air discharge from compressor or turbine into regenerator.

2 Effect of flow unbalance in passages which produces a material unbalance between cold fluid and hot fluid. This is of particular significance in heat exchangers of high NTU . The effect is not shown when testing with steam because of the unlimited amount of heat available from the condensing steam.

3 Effect of variations in manufacture on heat-exchanger performance—such as wear of dies.

If a test code is adopted as suggested by the authors, it might be advisable to arrange for a better check on pressure drop. This could be done by building a separate core for pressure-drop measurements. The "pressure-drop" core could be built to the same dimensions as the other core but arranged with all passages flowing in the same direction. This would give an area ratio at entrance and exit very close to unity. If such an arrangement is not possible, then a longer flow path could be used when testing for pressure drop. While there will always be some question as to whether the "heat-transfer" core and the pressure-drop core are of identical construction, the uncertainty can be reduced by suitable fabricating procedures. Also, since there are some fifteen to twenty-five individual passage sections there is a reasonably good averaging of fin variations.

J. J. DINAN.³ The information and data presented by the authors in these papers help to fill a need which exists in the field of heat-exchanger design. The paper takes the initiative in recommending a test apparatus and technique for obtaining accurate basic heat-transfer and flow-friction data for heat-exchanger surfaces. Also, it reports additional data which may be extrapolated to designs of compact heat exchangers.

Undoubtedly, the authors have put considerable thought into the design of the test apparatus reported herein. The estimated over-all accuracy of the data obtained and the excellent heat balances attest to this. Fig. 15, Part I of this paper, provides a check on the accuracy of the authors' methods. Comparison is made between data reported by the authors and that obtained by the U. S. Naval Engineering Experiment Station. Since the two test setups are, in general, similar, convincing evidence is provided for the reproducibility of test data if the authors' recommended technique is employed.

The friction-factor characteristic of the surfaces reported in this paper is defined by the friction factor f versus the Reynolds number. Evaluation of f is based upon the Fanning equation for flow in tubes. The application of this analogy to the plate-and-fin type of surface reported herein appears justifiable. One might expect the analogy to break down when applied to flow over the flat-tube type of surface. The curves in Fig. 6, Part 2 of this paper, do not bear this out since the friction-factor curves for the "finned, flat-tube" surfaces are similar in shape to the "plate-and-fin" surface designated as 1986. However, extension of the analogy to all heat-exchanger surfaces cannot logically be done. Test of a "plate and pin-fin" core at the Engineering Ex-

² Elliott Company, Jeannette, Pa. Mem. ASME.

³ U.S.N. Engineering Experiment Station, Annapolis, Md.

periment Station, showed that the analogy to flow over banks of tubés is applicable.

In comparing the heat-transfer and friction characteristics of different surfaces, the most significant comparison would seem to be a plot similar to Figs. 9 and 10, Part 2 of this paper. These figures make the comparison on a bulk or volumetric basis. Another comparison can be made purely on a heat-transfer-area basis. Possibly the plot might be extended to include the weight factor.

CLYDE SIMPELAAR.⁴ This paper, together with the individual project papers on the various surfaces tested at Stanford University laboratory, contributes materially to the literature on interrupted fin surfaces.

The authors suggest that it may not be advantageous to decrease louver spacing below $\frac{3}{4}$ to $\frac{1}{4}$ in. While certain of the data appear to bear this out, there is another directly associated condition, namely, the distance between in-line surfaces, which is not evaluated. In this it should be considered that the effect of spacing in the louvered-fin design which incorporates a surface configuration is probably different from that for a plain flat strip.

To consider then, only the uncounted strip fins such as those tested and reported in the original paper of Norris and Spofford, while the heat-transfer coefficient may increase with decrease in strip width, the coefficient may also decrease with decrease in distance between trailing and leading edges of the in-line strips so that the latter effect may substantially nullify the former. Both of these conclusions appear to be supported in the original paper mentioned, in which note should be made of the fact that without a modification of the definitive geometry (D_s), the performance of strip fins staggered by three's was substantially better than the performance of strips staggered by two's.

The strip-fin design identified as $\frac{3}{32}$ -12-22 in the present paper was tested in the Modine laboratory using a test core with a single air-side pass 6 in. high \times 3 in. in air-flow length. Heat-transfer tests of this sample correlated with those of the larger core tested at Stanford to within about 1 per cent. In order to verify what we have termed the "proximity effect" of in-line surfaces, an identical core was built except that in each channel fin alternate pairs of strips were removed at their base, increasing the distance between in-line surfaces from $\frac{3}{32}$ to $\frac{9}{32}$ in.

Tests of this core showed a gain in the Stanton-Prandtl group of 14 per cent at an N_{Re} of 1000, and 6 per cent at an N_{Re} of 10,000. Norris and Spofford showed an increase of 11 per cent in heat transfer for stagger by three's versus two's at an air flow of 1000 fpm. Other tests which were made indicated that this effect is significant over a wide range of distance between trailing and leading edges.

It appears possible, therefore, to obtain the advantage of the use of narrow strip fins if these are staggered by three's or four's so that the distance between strips is increased beyond the severely critical range. To correlate the performance, a Reynolds number based upon either the hydraulic radius or fin strip width or perimeter is not completely definitive and an "effective

Reynolds number" should be used which would take into consideration the "proximity effect" of in-line surfaces.

AUTHORS' CLOSURE

The authors' objectives in presenting this paper were to make available accurate basic heat-transfer and flow-friction data for a number of compact heat-exchanger surfaces which might find application in numerous systems where compactness is desired, including the gas-turbine heat exchangers. Whether or not any of these surfaces are suitable or desirable for the gas-turbine regenerator is for the regenerator designer to determine. The basic data presented here are not definitive and will only assist in this decision. It was not the objective of this paper to provide the designer with any criteria for the selection of an optimum surface for any particular application. In this regard the authors fail to see any "differences in viewpoints" between themselves and Mr. Aronson simply because the authors did not in this paper present any viewpoints on how gas-turbine regenerators should be designed.

Mr. Aronson's remarks regarding the shape problem when using low-density fluids are very well taken, and this aspect is discussed at some length by the authors in reference (2). However, he infers that for a given gas-turbine plant there is something of a definite physical limitation in the over-all compactness of the regenerator, and attempts to devise more compact units are doomed not to meet with success. The authors feel that such generalizations are not warranted at this time.

The effect of such things as complex flow patterns and flow unbalance in the passages can best be determined by tests of actual operating systems. It is hoped that manufacturers will make such data generally available.

A pressure-drop test core having an entrance and exit area ratio close to unity and long flow passages would be very desirable although, of course, adding considerably to the cost and time of the test program.

Mr. Dinan objects to the use of the Fanning friction factor f for other than tubular surfaces. As a matter of fact, it does not make any difference how the friction factor is defined providing that the same definition is used in the application and providing that it is applied to the same surface or to a geometrically similar surface. The only advantage of one method of presenting the friction characteristics of a surface over another occurs when attempting to generalize a correlation to cover variations in geometry. No such generalization was attempted in this paper. The friction factor and hydraulic radius were defined in the same manner for all the surfaces as a matter of convenience in applying these data. This definition was also used by Norris and Spofford in their pioneer paper, reference (10).

There are undoubtedly many improvements which can be made in the performance of heat-exchanger surfaces such as discussed by Mr. Simpelaar. The authors are presently conducting an investigation of the basic mechanisms of heat transfer and flow friction in complex flow passages with the hope that a better understanding of the basic mechanisms will lead to the development of more effective surfaces.

Calibrations of Six Beth-Flow Meters at Alden Hydraulic Laboratory, Worcester Polytechnic Institute

By L. J. HOOPER,¹ WORCESTER, MASS.

Six Beth-Flow tubes were calibrated by means of a volumetric tank at the Alden Hydraulic Laboratory to determine their suitability as flow-metering elements. Four of the six meters tested had practically the same coefficients with flow in either direction. The flow coefficients were constant above a Reynolds number of 100,000. Further tests are necessary to determine manufacturing tolerances and the effects of disturbed flow due to various types of piping arrangements.

THE purpose in calibrating the six Beth-Flow meters, discussed in the paper, was to determine their operating characteristics as a preliminary survey of the usefulness of this type of meter.

APPARATUS

Cross sections of the six meters tested are shown in Figs. 1 to 6, inclusive. It is noted that the meters differ from each other with respect to their upstream-throat diameter ratio and in the piezometer arrangements. Three of the meters were designed for installation in a 6-in. pipe and three in a 4-in. pipe. These and further details of the meter designs can be seen in the illustrations.

The calibration tests were performed in the lower basement of the main building of the Alden Hydraulic Laboratory. A 3-ft diam tank served as distribution center to reduce velocity effects at the entrance to the test section. The 12-in. supply from the laboratory pipe was connected near the top of the tank. To this was bolted an 8-ft length of 12-in. pipe. The test section of pipe, either 4 or 6 in. diam, was connected to this 12-in. pipe by means of a reducing flange. The approach pipe to the meter was approximately 25 ft long. The discharge from the meter was conducted to a switchway near a volumetric tank. This volumetric tank was 3 ft wide, 6 ft deep, and 22 ft long. It was calibrated carefully, immediately before the test, by means of a weighing tank. The details of the piping arrangement can be seen in Fig. 7.

The differential pressures developed by the flow meters were measured with three types of differential manometers, according to the pressure range required. Differential pressures from 2 ft to 25 ft were measured with a barometric type of mercury manometer which was calibrated by a water column prior to the test. Differential pressures from 0.2 ft to 4 ft were measured with a water-and-air manometer, which had a well connected to one side so that the deflection occurred in one manometer leg. Small differential pressures were measured with a micromanometer in which the deflection was measured in water columns 2 in. in diam.

Contributed by the Research Committee on Fluid Meters, and presented at the Annual Meeting, New York, N. Y., November 27-December 2, 1949, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society. Paper No. 49-A-38.

Point gages brought up underneath the water surface indicated the water levels in the customary manner for hook gages. The difference in elevation between the two point gages was measured with an Ames dial gage, reading to 0.0001 in. The upper limit of deflection with this manometer was approximately 4 in.

PROCEDURE

In preparing a meter for a test it was first carefully cleaned with carbon tetrachloride and clean wiping rags, to be sure that the interior surfaces were entirely free from grease. The upstream flange joint of the meter was made tight with a thin film of grease so as to avoid the possibility of a gasket sliding in the pipe and disturbing the flow in any manner. After the meter was bolted in place the line was filled with water, and all air pockets were blown out by means of suitable blowoffs both in the line and in the piezometer connections to the manometer that was in use. The proper operation of the manometer was checked by being sure that a zero deflection occurred on the manometer with zero flow. This static check was repeated frequently during the course of a test.

In preparation for a particular test the desired flow was first set and allowed to run to waste for 5 or 10 min to insure steady test conditions. When everything was in readiness, a measuring run was started on the volumetric tank by switching the discharge into the tank and simultaneously starting a calibrated stop watch. An observer on the manometer took readings of the deflection continuously throughout the discharge-measuring run. These readings were recorded on an adding machine which made it possible to secure from 40 to 100 readings of deflection for each test run. When the volumetric tank was nearly full the discharge was switched to waste, and the timer stopped. The length of the timing run varied from approximately 500 sec at the low flows to about 100 sec at maximum discharge. After the run was completed, the flow was adjusted at the next test value, and the test data were computed.

After a complete calibration curve had been obtained on the meter with the flow in the forward direction, the meter was taken out of the line and was reinserted so that the meter was in the reverse direction. A second complete calibration was then made under these conditions.

COMPUTATIONS

In computing the coefficients of the meters the actual discharge, as measured by the volumetric tank, was divided by the theoretical discharge computed from the meter deflection. The actual discharge was computed as follows:

$Q_{\text{actual}} = \text{volume divided by test time in seconds}$

The theoretical discharge for all of the meters was computed using the nominal dimensions of a meter, thus

$$Q_{\text{theoretical}} = A_1 \sqrt{2g(h_1 - h_2)} / \sqrt{R^4 - 1}$$

In the case of meter SK No. 1, the theoretical discharge was computed from the relationship

$$Q_{\text{actual}} = K \times H^{0.476}$$

FIG. 1 SK 1 BETH-FLOW TUBE TYPE V;

 $R = 1.72:1$

FIG. 6 SK 6 BETH-FLOW TUBE TYPE D;
 $R = 2.0:1$

where K includes the discharge coefficient as well as all constant terms.

RESULTS

The results of these tests are shown in Figs. 8 to 12, inclusive. Two of the meters, namely, No. 2 and No. 6, were not given a final calibration, and the results have not been included. These two meters did not show the same coefficients with reverse flow. Time was not taken to determine the reason for the differences inasmuch as this work could be better investigated along with other factors in a more complete investigation.

As may be seen from the curve sheets, the other four meters have practically the same coefficients for the flow in either direction. In all four cases the coefficient reaches a constant value

with a Reynolds number of approximately 100,000, based on the throat velocity. This corresponded to a throat velocity of very nearly 6 fps.

The coefficient continued constant to as high a value of throat velocity or Reynolds number as could be reached with the test setup. In the case of flow tubes No. 1 and No. 3, this was 2.3 cfs. In the case of No. 5, a discharge of nearly 3.2 cfs was reached.

In the case of flow tube No. 5, a poor set of readings was obtained on one test setup. In searching for the trouble with this particular calibration the question arose as to the stability of the point of separation in the exit tube. Two calibration curves were run, one with the entire inner surface of the tube very lightly greased by rubbing the surface with greasy hands. In the second test the inner surface was cleaned with carbon tetrachloride.

FIG. 7 ARRANGEMENT OF TEST PIPING

FIG. 8 SK 1 BETH-FLOW TUBE TYPE V; $R = 1.11:1$ FIG. 9 SK 3 BETH-FLOW TUBE TYPE VD; $R = 1.46:1$

FIG. 10 SK 4 BETH-FLOW TUBE TYPE D; $R = 1.84:1$ FIG. 11 SK 5 BETH-FLOW TUBE TYPE VD; $R = 1.72:1$ FIG. 12 SK 5 BETH-FLOW TUBE TYPE VD; $R = 1.72:1$

As may be seen in Fig. 12, the nature of the surface had a distinct effect in the higher ranges of discharge. With the greasy surface the coefficient gradually decreased from a normal value of 1.452 to 1.392, a difference of 4.1 per cent. This test was of interest in that it indicated the nature of the flow in the downstream section of the tube. In so far as accuracy of the tube is concerned, the test is undoubtedly of greater interest from a laboratory point of view than that of a commercial installation. In the laboratory the meter is normally calibrated very soon after it has been installed and the possibility of obtaining a partially greasy surface is very good. In commercial operations the tube is normally being used continually for the measuring of a single fluid, i.e., either water or oil, and the possibility of a lowered coefficient is practically negligible.

It must be remembered that the purpose of these tests was to determine the possibilities of these flow tubes as flow-measuring elements. This report therefore is of a very preliminary nature and indicates that these tubes do possess possibilities as flow-measuring devices. It is realized that considerably more research must be done with these tubes to determine the manufacturing tolerances and the effects of disturbed flow which attend various types of installations. It is presumed that the results of such a research program will be made available in the near future.

CONCLUSIONS

As a result of these calibration tests, certain designs of Beth-Flow tubes have been found to possess a constant coefficient

over a range of Reynolds numbers from approximately 100,000 to approximately 800,000. These meters were found to have the same coefficient for flow in either direction through the meter. Further research is necessary to determine manufacturing tolerances and effects of installation on the meter performance.

Discussion

M. M. BORDEN.² It may be of interest to note the differences of throat diameters for conventional Venturis (with approximate coefficient values as noted) and the Beth-Flow tubes with their coefficient values taken from the flat part of the curves in the paper.

Each tube of a given size is equated for a common (Q) quantity and differential head produced by it, as given in Table 1.

The relatively small differences of diameter of the throat constrictions given in Table 1 seem not to warrant the added cost of the Pitot bodies, as in sketch Figs. 4 and 6 of the paper, with the possible stoppage of their impact openings, or of the uncertainty of the effects of a change of velocity curve (with upstream roughness) upon the others.

The difference in head loss for a given size of constriction would

TABLE 1 CONVENTIONAL VENTURIS AND BETH-FLOW TUBES COMPARED

SK	Assumed C_d	Size Beth-Flow, in.	β	Equivalent Venturi, in.	C_d assumed	β	Difference Venturi throat and Beth-Flow throat, in.
1	0.86	$4 \times 3\frac{3}{4}$	0.906	4×3.556	0.90	0.889	-0.069
3	1.3	$4 \times 2\frac{1}{4}$	0.688	4×3.051	0.975	0.763	+0.301
4	0.92	$6 \times 3\frac{1}{4}$	0.542	6×3.153	0.9825	0.526	-0.097
5	1.46	$6 \times 3\frac{1}{2}$	0.583	6×4.129	0.9825	0.688	+0.627

surely be favored by the action of the diverging Venturi cone. If this be omitted, the loss of head need not be seriously greater than with a belled outlet from the Venturi throat.

It would appear that the use of a Pitot opening in a constriction could be better applied by placing the Pitot opening as far from the wall of the constriction as is convenient so it would be definitely located in the flat part of the velocity curve and in a region where least affected by upstream roughness or whirling flow.

Fig. 13, herewith, illustrates a type of Venturi-Pitot combination which has been used by the writer's company.

The curve showing relation of Venturi throat—Pitot differential to the normal main and throat differential are as shown in Fig. 14. With such a Pitot combination it is also possible to revolve the Pitot tube for removal of an obstruction; or to remove it for inspection; or to rotate it through such an angle as would produce a slight change of differential—all while delivering both differential pressures from a central piece.

FIG. 13 VENTURI-PITOT COMBINATION

FIG. 14 CURVE SHOWING RELATION OF VENTURI THROAT—PITOT DIFFERENTIAL TO NORMAL MAIN AND THROAT DIFFERENTIAL

W. S. PARDOE.² This discussion is in no way a criticism of the author and the Alden Laboratory at Worcester Polytechnic Institute. The writer has the highest appreciation of the work and ideas of this laboratory but it is written in response to the author's suggestion of further studies and in answer to a statement in an article published in *The Engineering News-Record* of August 18, 1949, entitled, "New Flow Meter Cuts Costs, Simplifies Installation Problems," by R. E. Tarring, as follows:

"Its short length permits insertion in complicated pipe systems and at the most advantageous point on the hydraulic gradient. Accuracy is not lost and expensive revamping of the system is avoided. Straight pipe-runs before or after elbows, tees, crosses, or other fittings—are not required;" also, "The streamlined interior of the meter-Low main-to-throat (high Beta) gives negligible unrecovered pressure loss." Other claims have been made, but these will suffice.

Fig. 15 of this discussion is a schematic sketch of the Hydraulic Laboratory of the Civil Engineering Department of the University of Pennsylvania in Philadelphia, Pa. It consists of a sump, pumps, cast-iron pipe system, 5-ft 6-in.-diam stand pipe, test pipe lines, test meter, and two 16,000-lb weighing tanks. The maximum pumping and weighing rate is 12 cfs (5400 gpm.).

Fig. 16 shows the three differential gages; the first, a 3-in. hook gage measuring up to 0.6 ft reading to 0.0001 ft.

²Professor of Hydraulic Engineering, University of Pennsylvania, Philadelphia, Pa.

The second is a direct-reading air gage used from 0.6 ft to 4.5 ft.

The third is a direct-reading mercurial gage used for heads greater than 5 ft.

Fig. 17 shows the 8 × 10 in. Beth-Flow tube.

Fig. 18 is a cross section of a test of a 6-in. Gentile multiple Pitot tube showing a log-log head—(velocity in 6-in. pipe) curve the empiric equation of which is $V = 4.3 h^{0.4875}$. Note that all the points fall on the line due to the very small scale.

Fig. 19 shows the same data put in terms of C in $V = C\sqrt{2gh}$ and the velocity in the 6-in. pipe. Note the scatter of the points being plus and minus 0.6 per cent; the lost head is 21 per cent of the working head.* The laboratory has an error of plus and minus 0.1 per cent as can be seen in Fig. 20, which is a test of a 12 × 8 1/4 in. ($\beta = 0.69$) Venturi meter. Note that the lost head equals 10 per cent of the Venturi head; if β were 0.75 the lost head would be less.

Fig. 21 is a log-log throat velocity—Venturi head curve for Mr. Gentile's information. The Gentile tube shows a scatter of points six times that of the Venturi meter tested in the same setup in the presence of both the manufacturer and the customer. This must be attributed to the location of the multiple Pitot tubes which pick up fluctuations of velocity due to turbulence and minor vortexes near the wall. The manometers showed much wider fluctuations and surges than those of the Venturi meter.

Fig. 22 shows a traverse in a 4-in. pipe, and Fig. 23 shows a

FIG. 15 SCHEMATIC ARRANGEMENTS OF HYDRAULIC LABORATORY

FIG. 16 DIFFERENTIAL GAGES

FIG. 18 TEST OF 6-IN. GENTILE MULTIPLE PITOT TUBE

FIG. 19 TEST OF 6-IN. GENTILE MULTIPLE PITOT TUBE

FIG. 20 TEST OF 11.956 X 8.2285-IN. VENTURI TUBE T 4349 (Leeda and Northrup Company; Philadelphia Electric Company, Richmond Station.)

traverse in an 8 in. pipe immediately following a series of flanged decreases from 24 in. to 8 in. diam. It is evident these traverses would have a profound effect on the coefficient as the Pitot tubes are acted on by the velocity near the wall. Fig. 22 should give a high coefficient due to the low head, and Fig. 23 a low coefficient due to a high working head if the mean velocities are equal.

The effect of an eccentric traverse such as occurs after elbows should increase the working head and decrease the coefficient due to the fact that the square of the mean velocity is less than the mean of the squares of the individual velocities.

With these ideas in mind the writer seized the opportunity (of the presence in his laboratory of an 8 X 6-in. Beth-Flow tube sent in for test by the city of Philadelphia) to make the following tests of the "effect of installation on the coefficient of the 8 X 6-in.

FIG. 21 TEST OF 11.596 \times 8.2285-IN. VENTURI TUBE NO. T 4349 (Leeds and Northrup Company; Philadelphia Electric Company, Richmond Station.)

FIG. 22 TEST OF PITOT TUBE IN 4.281-IN. PIPE COUNTERSUNK POINT

FIG. 23 COUNTERSUNK PITOT TUBE IN APPROXIMATELY SHOOTING FLOW

Beth-Flow tube," and compare them with similar data for the Venturi meter of similar proportions.

Fig. 24 is a log-log head-discharge curve for this 8 \times 6-in. Beth-Flow tube. Again, note how all the points fall on the line

FIG. 24 TEST OF 8 \times 6-IN. BETH-FLOW TUBE FOR PHILADELPHIA

FIG. 25 TEST OF 8 \times 6-IN. BETH-FLOW TUBE FOR CITY OF PHILADELPHIA

FIG. 26 BETH-FLOW TUBE WITH 32-IN-LONG CROSS-STRAIGHTENING VANE; EFFECT OF INSTALLATION

with the following equation: $cfs = 1.47 h^{0.51}$. These curves are very deceptive.

Fig. 25 gives the same data plotted as coefficient C against throat velocity. Note again the scatter of points, and the log-log curve gives no hint of the form of this coefficient curve. The lost head equals 12.1 per cent of the working head. Also, the setup has no straightening vanes. The average of ten values of the coefficient at 10, 20, and 100 per cent of the integrator range is 0.9392.

Fig. 26 shows the same setup with a 32-in-long cross-straightening vane 20 ft ahead of the Beth-Flow tube, the average coefficient being 0.9539 or 1.54 per cent above Fig. 25. This setup has been used as a basis of comparison for all the others. Note that the normal turbulence and slight vortexes always present in

FIG. 27 TEST OF 8 X 6-IN. BETH-FLOW TUBE WITH TWO CROSS-STRAIGHTENING VANES; EFFECT OF INSTALLATION

FIG. 28 TEST OF 8 X 6-IN. BETH-FLOW TUBES; EFFECT OF INSTALLATION

FIG. 29 EFFECT OF INSTALLATION ON VENTURI METERS

piping systems produce an error of 1.54 per cent. It looks as if this meter extends from the lower end of our pump suction through the pumps and cast-iron piping system into the stand-pipe through the 24 in. to 8 in. reducers and 20 ft (30 diam.) of 8-in. pipe, that is, it is very sensitive to the small disturbances in the flow.

Fig. 27, a cross-straightening vane 24 in. was added immediately ahead of the meter giving a coefficient of 0.9411, being 1.34 per cent less than Fig. 26. This latter vane evidently flattened the pipe traverse at the meter.

Setups in Figs. 25, 26, and 27 would all produce the same coefficient with an 8 X 6 in. Venturi meter, see Fig. 39.

Fig. 28, the Beth-Flow tube was placed immediately after the 24 in. to 8 in. flanged reducers; this gave an average coefficient of 0.9095 or minus 4.65 per cent. The coefficient of the Venturi meter under a similar setup decreased 0.098 per cent (see Fig. 29).

In Fig. 30 the Beth-Flow tube was placed after a 90-deg short-radius elbow, thus passing an eccentric traverse into the tube; the average coefficient was 0.8529 or minus 10.6 per cent. In Fig. 31 a piece of 8-in. pipe 8 in. long was placed between the elbow and the meter. The average coefficient dropped to 0.8381 or minus 12.1 per cent.

Fig. 32 indicates the 8 X 6 in. Venturi meter would be plus 1.78 and 1.09 per cent, respectively.

In Fig. 33 the Beth-Flow tube was placed immediately after two short-radius 90-deg, 8-ft elbows in planes at right angles. The average coefficient was 0.8366 or minus 12.3 per cent.

In Fig. 34 an 8-in.-long piece of 8-in. pipe was inserted between the second elbow and the Beth-Flow tube; the average co-

FIG. 36 TEST OF 8 X 6-IN. BETH-FLOW TUBE; EFFECT OF INSTALLATION

efficient was 0.8642 or minus 9.4 per cent. Fig. 35 shows the corresponding values for the 8 X 6 in. Venturi meter to be plus 0.22 and 0.07 per cent, respectively.

In Fig. 36 the Beth-Flow tube was placed immediately after a 6-in. to 8-in. flanged increaser. The coefficient was 0.9333 or minus 2.16 per cent. In Fig. 37 an 8-in. pipe 16 in. long was added between the enlarger and the Beth-Flow tube; the average coefficient was 0.9136 or minus 4.23 per cent. From Fig. 38 the corresponding values for the 8 X 6 in. Venturi meter were plus 7.80 and 3.75 per cent, respectively.

In order to bring out the effect of a rough upstream pipe, one layer of 1/4-in. mesh #18 wire in the form of a cylinder 8 in. OD

FIG. 37 TEST OF 8 X 6-IN. BETH-FLOW TUBE; EFFECT OF INSTALLATION

FIG. 38 EFFECT OF INSTALLATION ON VENTURI METERS

FIG. 39 TEST OF 8 X 6-IN. BETH-FLOW TUBE; EFFECT OF INSTALLATION

FIG. 40 EFFECT OF INSTALLATION ON VENTURI METER

and 36 in. long was placed immediately before the Beth-Flow tube as shown in Fig. 39. The average coefficient rose to 1.0297 or plus 6.9 per cent; the coefficient varied from 0.98-1.00. No similar test was made on the 8 × 6 in. Venturi meter.

Fig. 40 shows the effect on the Venturi meter of a cross-straightening vane after two elbows in planes at right angles. At six diameters we get the normal coefficient, therefore they do not affect the Venturi meter; see Fig. 27.

Fig. 41 is a collection of the foregoing data for comparative purpose.

The writer feels that if the Beth-Flow tube had been invented first what an earth-rocking invention Clemens Herschel's Venturi meter would have been.

VINCENT GENTILE, JR.⁴ Calibration of the 6 × 3½ in. type D flow tube at the Alden Hydraulic Laboratory, covered the following ranges:

Quantity.....	0.0249 cfs-2.517 cfs	(100-1)
Velocity.....	0.437 fps-44.0 fps	(100-1)
Head.....	0.0473 in. water-375 in. water	(7900-1)
Reynolds No....	7800-970,000	(124-1)

The coefficient of discharge, computed on the square-root basis, varies from approximately 0.925 at 970,000 to 0.90 at 100,000. Below that, its value drops off more rapidly.

Calibration of the 8 × 6 in. tube of the same type, at the University of Pennsylvania, covered the following ranges:

Quantity.....	0.196 cfs-6.03 cfs	(31-1)
Velocity.....	1 fps-31 fps	(31-1)
Head.....	0.203 in. water-196 in. water	(965-1)
Reynolds No....	40,000-1,300,000	(31-1)

Using the same basis as in the foregoing, the coefficient varies from 0.95 at 1,300,000 to 0.925 at 100,000, and 0.96 at 50,000. It should be noted, however, that when differentials are plotted versus capacity on log paper, all points lie on straight lines, indicating that over the entire ranges covered by these tests, the discharge coefficients remain constant if differentials are expressed to powers of velocity corresponding to slope of curves, Figs. 42 and 43 of this discussion.

Head meters, in general, do not, even for limited ranges, follow the square-root law exactly. On the other hand, practically any primary device will show a constant coefficient, if head is expressed to the proper exponent, over a range far in excess of the requirements of commercial metering, and broad enough to satisfy the most exacting demands of laboratory test work.

⁴ Brooklyn, N. Y.

FIG. 41 SUMMARY OF TESTS ON 8 × 6-IN. BETH-FLOW TUBE FOR EFFECT OF INSTALLATION

The head developed by a primary device can be expressed by the equation

$$H = K h_v R^x$$

in which

K = calibration constant

h_v = velocity head $V^2/2g$

R = Reynolds number VD/ν

x = experimental exponent

By a simple transformation the formula for discharge becomes

$$Q = \frac{CA(2gH)^n Z^{(1-2n)}}{D^{(1-2n)}}$$

in which

C = discharge coefficient = $1/K^n$

A = area

Z = kinematic viscosity

D = diameter

$$n = \frac{1}{2 \times x}$$

For a meter of a given size, the formula can be simplified to

$$Q = C^* A (2gH)^n Z^{(1-2n)}$$

and for a given meter and fluid the expression finally reduces to

$$Q = C^* A (2gH)^n$$

The exponent n appears to vary with the type of primary device, with the D/d ratio, and probably with other factors that we know nothing at all about. It is slightly greater than $1/2$ for the type D flow tube, the nozzle, and the Venturi, and slightly less than $1/2$ for the orifice, and for the V and VD flow tubes.

If these test data are analyzed in this fashion, the type D flow tube has a demonstrated range of 30 to 1 in one case, and 100 to 1 in the other. The upper limits were governed in each case by the maximum flow capacity of the laboratory. From the direction of the log plots, it can be seen that the coefficients would have continued constant considerably beyond these ranges. It is

FIG. 43 LOG-LOG PLOT CALIBRATION OF 6 X 3 1/4-IN. SK 4 FLOW TUBE AT ALDEN HYDRAULIC LABORATORY

important to note that, on this basis, the coefficient of the 6 x 3 1/4 in. tube is virtually constant for all Reynolds numbers above 11,000 (lowest point on log plot), while on the square-root basis, the coefficient is only approximately constant for Reynolds numbers above 100,000. Thus the effective range of a meter is considerably increased by the simple expedient of expressing head to the proper power of velocity.

Logarithmic plots are useful, not only for furnishing a more rational basis for the study of fluid flow, but also to indicate obvious errors of measurement and observation.

The essential difference between the flow tube and other head meters is that total pressure differentials are used instead of static pressure differentials. It is submitted that this basis is more direct and less subject to error. The static pressure at a given section is equal to the total pressure minus the effective velocity pressure. But the effective velocity pressure varies with velocity distribution across the section and with the magnitude of rotative and translative components. Thus it is possible, under certain conditions, to obtain different static pressure readings for the same average flow across a section. In some cases the difference is small, in others it is appreciable. In the flow tube the static pressure cancels out whatever its value and whatever the factors contributing toward it. In the V and D tubes,

and even in modified designs of the VD tube, all readings are taken at the same section, the static pressure drops out of the equation, and the differential becomes a function of axial-velocity components, which, in turn, are proportional to mass flow. Moreover, since all readings are taken at the throat, where the velocity distribution is relatively flat, the effect of disturbed flow due to fittings is minimized. Further, since readings are taken all around the periphery, a high reading on one side will be partly compensated for by a correspondingly lower reading on the other. There is of course a theoretical error due to the fact that the average of the squares is not equal to the square of the average, but tests indicate that this is small and well within the required accuracies of commercial installations.

Tubes with a high D/d ratio will be least affected by installation. Also, the type D tube, due to straightening effect of streamlined nozzles, will perform more consistently than the others. Figs. 44 and 45, herewith, show head-capacity curves for

FIG. 44 CALIBRATION OF 6 X 3 1/4-IN. TYPE D FLOW TUBE FOR INSTALLATION

FIG. 45 CALIBRATION OF 6 X 3 1/4-IN. TYPE VD FLOW TUBE FOR INSTALLATION

the $6 \times 3\frac{1}{4}$ in. type D, and the $6 \times 3\frac{1}{2}$ in. type VD tubes (SK4 and SK5, respectively, in the paper), downstream from a compound elbow with a reducer between one elbow and the other. Even under these extreme conditions, there is no apparent change in coefficient. It is not concluded from this that straight-run calibrations can be used indiscriminately for any application, but rather that a flow tube of proper design will perform satisfactorily near an elbow or other fitting, if previously calibrated in a piping arrangement simulating the actual installation.

C. G. RICHARDSON.⁵ The writer served on the first Fluid Meters Committee. After 6 years of discussion, Part I of the committee's report was published. Later, a new committee produced Part III, dealing, in part, with the influence of installation on various types of commercial meters. It would seem that it has been amply proved that there is a great variation in the value and character of the Beth-Flow coefficients under approach conditions which have little, if any, effect on a standard Venturi tube. One does not see how the performance of the Beth-Flow can possibly be predicted unless it is volumetrically tested in a piping assembly duplicating the size, arrangement, and flow range of the final installation.

I. R. SCHWARTZ.⁶ An important criterion in evaluating any primary device of the head type is the pressure differential produced with a given flow for operating the secondary instrument. A simple analysis indicates that the Beth-Flow tube of the type with little or no contraction should produce much lower heads than any of the standard methods, viz., Venturi tube, nozzle, and orifice, for β ratios below about 0.8, and compares increasingly less favorably as the β ratio is decreased in the latter. For high enough initial velocities the Beth-Flow tube could provide adequate working-pressure differentials with almost no friction loss, but under these conditions would show little advantage over a simple Pitot meter. Both require individual calibration, in itself a rather serious drawback.

For low initial velocities it would seem necessary then to use a type with some contraction. Here the Beth-Flow tube should yield somewhat higher pressure heads than the standard device of the same contraction, but its friction loss is now comparable to that of the latter.

From these standpoints the writer fails to find wherein the Beth-Flow tube is superior, if not indeed inferior, to the usual more simple primary devices.

AUTHOR'S CLOSURE

The discussions of this paper add to the knowledge of the performance of Gentile-Flow tubes and are greatly appreciated. Professor Pardoe's test work in particular is a material contribution to the performance of one Gentile-Flow tube for flow conditions departing from the ideal. There are one or two points of his discussion that can be clarified slightly.

In Professor Pardoe's test results the performance of the two types of metering elements are compared on the basis of equal pipe diameters between the disturbing element to the inlet flange of the meter. This ignores the fact that the Gentile-Flow tube is much shorter than the Herschel Type Venturi Meter. If the comparison of performance were to take this into account the Gentile tube should be credited with the difference in length of the meters taken up with straight approach pipe between the disturbing element and the inlet flange of the meter. If this were done it would tend to reduce the magnitude of the deviations for

the Gentile Tube indicated in Professor Pardoe's table and make the comparison with the Venturi meter more favorable.

In test No. 11, the effect of pipe wall roughness on the performance of the flow tube is indicated, with a blank indicated for the performance of the Venturi. In our opinion the introduction of the screen wire along the wall of the pipe for several diameters upstream simulates to a degree the roughness effects that can be produced by tuberculation. The effect of pipe wall roughness on a Venturi coefficient was shown in one instance in a paper presented by Prof. C. M. Allen and the author, entitled, "Venturi and Weir Measurements." This paper was printed in *Mechanical Engineering* for June, 1935. It was shown at that time that the average Venturi coefficient for a 36×16 in. Herschel type meter started at .975 for a 36×16 in. Venturi meter when the penstock was clean. As the penstock and meter became more rusty the coefficient of the Venturi gradually dropped off to .954 in a period of 12 years. In 1934 a mossy growth was found developing in the penstock starting 25 ft upstream from the meter. The presence of this mossy growth dropped the coefficient from .954 to .945. Washing the moss from the penstock without disturbing the tubercles brought the coefficient back to the previously cited value of .954.

In the discussion of this paper Professor Pardoe cited the effect of tuberculation on a 12×6 in. Venturi meter in his own laboratory where the coefficient decreased from .976 with a clean pipe to approximately .962 for a tuberculated pipe after a period of approximately six years. It is seen therefore that there is some effect on a Venturi meter due to pipe wall roughness extending upstream. In this case, as in most of the other cases cited by Professor Pardoe, the effect on the Venturi coefficient is considerably smaller than the effect on the flow tube.

With respect to Mr. Gentile's use of the log-log plot of the deflection versus discharge for a flow tube, such a plot is customarily used to check an exponential formula. As Mr. Gentile points out, it is frequently found in hydraulics that by using a decimal power slightly different than a square or a square root, a formula is obtained in which the coefficient remains constant. The objection to this approach is that a formula involving a decimal power is usually less convenient to handle than one employing an even power. That, of course, is a matter of personal convenience and opinion. A log-log plot has a further advantage in that the results are presented with a constant accuracy, that is to say, a 10 per cent deviation from the curve at the lower range looks just as large as a 10 per cent deviation in the upper range which would not be true where deflection is plotted against discharge in rectilinear co-ordinates. Plotting the coefficient of the Venturi formula against throat velocity or Reynolds number also provides a curve in which deviations are shown with uniform accuracy over the range. In Professor Pardoe's presentation of coefficient values a space of one-half inch is customarily used to indicate a difference in coefficient of 1 per cent. To have a log-log plot of deflection against discharge indicate deviations with the same clarity would require a base length of 50 in. per cycle. It is seen, therefore, that where the presentation of results is to be made with a given constant accuracy the coefficient against throat velocity is a much more compact method than the log-log plot.

In closing, the valued discussions presented confirm the statement in the conclusion of the original paper that many more tests should be made before the coefficient of a Gentile flow tube can be predicted for various installation conditions. At the present time we quite agree with Mr. C. G. Richardson that the performance of a flow tube must be based upon a calibration duplicating the flow conditions of the final installation. Once calibrated, however, a Gentile-Flow tube should maintain its operating curve subject only to the effects of roughening of the pipe wall as stated above.

Latest Technique for Quick Starts on Large Turbines and Boilers

By J. C. FALKNER,¹ D. W. NAPIER,² AND C. W. KELLSTEDT,³ NEW YORK, N. Y.

The first quick starts made on the 1200-psi 900 F topping turbines at the Waterside Station were described in a paper⁴ presented in June, 1947. The purpose of the present paper is to review the high lights of the earlier presentation and to relate the developments since then.

A TYPICAL Consolidated Edison System daily winter load cycle is represented in Fig. 1. It shows late evening winter peaks of about 2,500,000 kw, and minimum loads of approximately 700,000 kw during the 12 to 8 watch. The system load factor for 1948 was 53.1 per cent. The extreme variation in generation and also the high rate of pickup in the morning hours from 5 to 9 o'clock will be noted. While many systems have topping units similar to those on the Consolidated Edison System, few, if any, have this great difference between maximum and minimum daily loads, and are faced with the necessity of shutting down some toppers nightly. By 1952 there will be a total of ten topping units on the system; six at Waterside, two at Sherman Creek, one at Hell Gate, and one at Hudson Avenue, with a total generating capacity of over 1,000,000 kw, including the power generated by their exhaust steam. Furthermore, the number of toppers which are now shut down nightly will be greatly increased in the early 1950's by the installation at East River Station of two 120,000-kw, 1450-psi, 1000 F General Electric condensing machines, one of which at least will run 24 hr a day.

QUICK-START PROCEDURE

The principle of the quick-start procedure is simple and consists of admitting steam into a turbine at a temperature equal to or slightly higher than the metal temperature of the turbine steam chest. With the turbine generator operating at a turning-gear speed of 3 rpm, the turbine can then as a matter of routine be brought up to speed and synchronized to the bus with absolute safety in 12 to 15 min. The present practice is to load the unit in such a way that the rate of increase in the turbine steam chest metal temperature will not be over 100 F per hr.

To determine metal temperature changes in the turbine structure during the starts, thermocouples were installed over various sections of the turbine shells. The isometric sketch given in Fig. 2 shows the locations of the thermocouples installed on

FIG. 1 CONSOLIDATED EDISON SYSTEM, GROSS GENERATION WINTER PEAK DAY FOR VARIOUS YEARS

No. 6, Westinghouse 65,000-kw unit at Waterside Station. Fig. 3 shows a comparison of steam and metal temperature changes in this machine during a quick and a normal start. Note, by observing thermocouple No. 1, how the quick start has practically eliminated the cooling which takes place during the normal or slow-start method. Fig. 4 shows another isometric sketch of No. 7 General Electric 65,000-kw unit with the locations of the thermocouples. Fig. 5 gives the comparative metal temperature change in No. 7 unit during a quick and a normal start. Again, notice in the quick start the absence of the cooling which takes place during the normal start.

Since the presentation of the first paper the practice of quick-starting topping units has been continued with improved technique, due mostly to better synchronizing of the operators' moves on the boilers, turbines, and high board. As of April 19, 1949, the number of quick starts made on the Waterside four topping units are as follows:

- 66 starts on No. 4—Westinghouse 53,000-kw unit
- 49 starts on No. 5—General Electric 53,000-kw unit
- 36 starts on No. 6—Westinghouse 65,000-kw unit
- 37 starts on No. 7—General Electric 65,000-kw unit

FIG. 2 (left) DIAGRAM SHOWING THERMOCOUPLES PEENED ON TURBINE CASING OF HIGH-PRESSURE UNIT NO. 6, WATERRSIDE STATION

INTERNAL CONDITION OF TOPPING UNIT AFTER 32 QUICK STARTS

Since the advent of quick-starting of topping units in April, 1946, the first opportunity which presented itself to observe the internal condition of one of these units occurred in 1948. It was brought about by an overhaul of No. 5 Unit at Waterrside, a 53,000-kw General Electric machine which, when removed from service, had had 46,000 hr of operation between November, 1942, and August, 1948. During this interval, No. 5 turbine underwent a total of 32 quick starts, 74 water washes, and 4 caustic washes. The inspection showed the spindle, buckets, nozzles, and diaphragms to be in exceptionally good condition. There was some evidence of very light spindle-shroud rubs on the leading edge, and the brightness of the rubs indicated them to be of recent origin. The thrust-bearing clearance was normal or 0.015 in., but the bearing fit which supports the thrust-bearing housing was worn and permitted an additional 0.017 to 0.020 in. axial movement of the spindle. Without a doubt, this wear together with the practice of water-washing caused the light rubs previously mentioned on the leading shroud edges. All nozzles, buckets, shrouding, and spindle were magnetically tested and no cracks were found. The spindle shaft, checked for truth, was within 0.001 in. From this inspection it was satisfactorily established to all concerned that the practice of quick starts and water-washing did not produce any detrimental effect on any part of the machine.

QUICK STARTS IMPROVE AXIAL DIFFERENTIALS

FIG. 5 COMPARISON OF QUICK AND NORMAL STARTS OF HIGH-PRESSURE UNIT NO. 7

during a recent quick start on No. 5 unit, also shows another very important factor in the quick-start procedure which could not be brought out in the initial presentation⁴ because of lack of instrumentation at the time of the earlier trials. On recent turbine installations the General Electric Company has furnished a differential-expansion recorder. The sensing element of the instrument consists of two magnetic coils mounted rigidly on the internal surface of the high-pressure-turbine exhaust-bearing pedestal with the pole faces of the coils set at given air gaps from

FIG. 6 (b) TURBINE METAL TEMPERATURES AND DIFFERENTIAL EXPANSION BETWEEN HIGH-PRESSURE SPINDLE AND CYLINDER DURING A QUICK START, HIGH-PRESSURE UNIT NO. 5, WATERSIDE STATION

the vertical faces of the solid coupling. With the spindle fixed axially in the front pedestal of the machine at the thrust bearing, the instrument records the relative change of internal axial clearances between spindle and cylinder during any operation. Because of its lighter mass and higher rate of heat absorption, the spindle length responds much faster to temperature change than does the heavy cylinder mass. Therefore, when a rapid cooling occurs, there is a possibility of rubbing on the entry side of the spindle blading. On No. 5 unit at Waterside Station, the differential-expansion recorder was installed in recent months and its magnetic coils were set with a governor-side air gap of 0.100 in., and a generator-side air gap of 0.150 in. With these settings the governor-side clearances of the first and last-stage wheels are 0.020 in. and 0.058 in., respectively. Note, in Fig. 6 (b), that there is absolutely no change in the axial relationship of spindle

FIG. 7 (left) TURBINE METAL TEMPERATURES AND DIFFERENTIAL EXPANSION BETWEEN HIGH-PRESSURE SPINDLE AND CYLINDER DURING WATER-WASHING OF HIGH-PRESSURE TURBINE BLADING

and cylinder, thus proving beyond question that the quick-starting method of handling the turbine after an overnight shutdown is superior to the older slow-start procedure.

Fig. 7 shows what happens to the axial clearance during an overnight water wash and slow start. Note that the governor side, or forward clearance, decreases continuously as the machine cools down, and then begins to increase as the cylinder starts to cool and shrink, thereby bringing the axial clearance toward normal. The latter part of the differential expansion line shows what would happen to the clearances of the machine if it were started after an overnight shutdown with the slower-starting method, namely, the forward clearance first increases and then gradually decreases as the cylinder approaches spindle temperature.

WATER-WASHING

To digress a moment on the subject of turbine water-washing; the machines at Waterside Station foul up over a short period of time because of the large make-up needed to replace the steam sent out to the New York Steam Corporation. For several years it was the practice to shut down a topping unit on week ends when its capacity had dropped 5000 to 6000 kw, and water-wash the

turbine blading at 400 to 500 rpm. Later it was found that a good wash result could be obtained by taking the units out of service overnight and injecting water while the machine was rolling at approximately 1000 rpm, gradually bringing the steam down to a saturation temperature, holding it saturated for 1 or 2 hr, and then gradually shutting off the water, bringing the machine up to speed, and increasing the steam temperature at a rate of 100 F per hr.

TRIALS AT SHERMAN CREEK

Success of the quick starts at Waterside Station led to further trials at Sherman Creek, where two 50,000-kw, 1600-psi, 950 F high-pressure units Nos. 9 and 10 are in operation. No. 9 unit is a Westinghouse machine which was installed in 1943, and No. 10 unit is a General Electric machine which was put in service in 1947. Each is supplied by a single boiler, rated at 1,000,000 lb of steam per hr.

All the quick starts made up to the present time at Sherman Creek have been on No. 9 unit, the first one being made on April 23, 1948. Since that time there have been 25 quick starts on this unit. No quick start has been made to date on No. 10

FIG. 8 (right) SUPERPOSED TURBINE-GENERATOR UNIT NO. 9, SHERMAN CREEK STATION (50,000-kw, 3600-rpm, 1600-psig, 950 F total temperature, 200-psig back pressure.)

unit because of boiler ignition difficulties. Experience at Waterside and the initial start at Sherman Creek indicated that it was not necessary to record any other temperatures but those of the steam temperature entering the turbine and the temperature of the outside metal of the governing valve chest ahead of the turbine nozzles. This latter point—point No. 2—is shown in Fig. 8.

Fig. 9 shows a section of No. 90 boiler. The steam passes from the superheater-outlet header to the turbine with only the turbine throttle in the circuit. Note the location of thermocouple No. 1 which gives the temperature of the steam entering the turbine and of the size of the drain line ahead of the throttle valve.

The boiler is tangentially fired with pulverized coal from three mills, each mill supplying one burner in each corner so that the four bottom burners are supplied by one mill, the four middle burners by the second, and the four top by a third.

Quick-starting of the single boiler unit at Sherman Creek introduced a different problem from that experienced at Waterside. The steam flow required to roll the topping turbines at full speed at Waterside is approximately 200,000 lb of steam per hr, and, at Sherman Creek, it is approximately 250,000 lb per hr. However, Waterside has had very little difficulty in obtaining a steam temperature at the start equal to that of the metal at the inlet of the turbine, because only one of the two boilers per unit is used at that time, and full-speed-no-load steam flow represents approximately 40 per cent of the full load rating of the Waterside boilers. However, at Sherman Creek, the full-speed-no-load steam flow is only 25 per cent of the full load rating of the boilers. This means that during the rolling period the superheater-outlet steam temperature at Sherman Creek is much lower than that obtained with the same flow on the smaller boilers at Waterside.

Fig. 10 shows the results of a slow start on No. 9 unit after a 4-hr shutdown. The rolling time after such a shutdown was 1 hr, and it can be seen that, after the throttle was opened and during the initial rolling period, the steam-chest metal temperature dropped during the first 35 min from 825 F to 570 F, or a total of 255 F, or again at a rate of 436 F per hr. It is also to be noted that the temperature fall was reversed 12 min after it had crossed the throttle-steam-temperature curve and rose from then on at approximately the same rate that it had fallen.

The quick-start procedure first used at Sherman Creek was similar to that at Waterside, but the firing of the boiler prior to

FIG. 9 NO. 90 BOILER, SHERMAN CREEK STATION

FIG. 10 SLOW START, NO OIL BURNERS, UNIT NO. 9, SHERMAN CREEK STATION, FEBRUARY 17, 1948

FIG. 11 (left) QUICK START USING NO OIL BURNERS, UNIT NO. 9, SHERMAN CREEK STATION, APRIL 23, 1948

FIG. 12 (left) QUICK START USING NO OIL BURNERS, UNIT NO. 9, SHERMAN CREEK STATION, FEBRUARY 28, 1949

the rolling of the turbine was purposely made intermittent in order to avoid a sudden increase in boiler pressure, which would have resulted in a saturation-temperature rate of rise in excess of 100 F per hour which, according to the boiler manufacturers, would produce objectionable stresses in the walls of the boiler drums. The mill supplying the upper burners was used in order to obtain as high a gas temperature as possible, entering the superheater.

Results of the first quick start made on this unit are shown in Fig. 11. The steam-chest temperature dropped 106 F from 676 F to 570 F in the first 10 min of the rolling period and then increased from 255 F to 825 F in the following 35 min. This was an improvement in the magnitude of the temperature drop, partly because of the fact that the steam temperature at the start was 675 F or 150 F lower than on the afore-mentioned normal start, but there was no improvement in the temperature rise, this being still at the rate of 437 F per hr. This indicated the necessity for altering the procedure so that the steam tempera-

ture would be increased as rapidly as possible until the steam-chest temperature was on the upward trend, and then doing everything possible to keep this temperature rise at a slow rate after reaching that point. This was achieved by deliberately lowering the temperature of the steam leaving the boiler before the unit was taken off the line to obtain a lower turbine steam-chest temperature for the next start, and then using high excess air in order to obtain a larger volume of gas at a higher temperature entering the superheater before the throttle was opened. In order to slow down the temperature rise after the throttle was opened, the air flow was decreased and the mill supplying the lower burners was started, in place of the one supplying the upper burners, after the steam-chest temperature had begun its upward turn.

The improvements resulting from this procedure are shown in Fig. 12, which is the result of another start where the initial temperature of the steam chest was 650 F and the temperature reduction was only 40 F to 610 F after the throttle was opened.

FIG. 13 (right) QUICK START USING FOUR AUXILIARY OIL BURNERS, UNIT NO. 9, SHERMAN CREEK STATION, MARCH 2, 1949

FIG. 14 (right) COMPARISON OF QUICK STARTS WITH OR WITHOUT OIL BURNERS

The temperature rise was 105 F in the first 20 min and only 200 F in the first hour. This of course was still not an ideal start, as it would have been preferable to have the temperature of the turbine at the time of its shutdown closer to its normal operating temperature. Then, if the initial steam temperature could have been brought up to this higher turbine-metal temperature at the start, the turbine-metal temperature change, from shutdown to load, would have been at a minimum. However, it had not been possible to obtain starting steam temperatures much above saturation up until this time.

It is felt that, due to the superheater design which is of the pendant type, steam condenses in the superheater elements during the bottled-up period, with the result that all but a few of the elements are full of water when it is time to start the unit. The steam drain provided in the main steam lead is too small to permit sufficient mass steam flow through the superheater to blow out the accumulated water and permit the superheater elements to act as designed, rather than as evaporating elements. As a result, the boiler pressure rose rapidly and soon reached a point

where the turbine throttle valve had to be opened, although the steam temperature was not yet equal to the turbine-metal temperature.

EXPERIMENTAL BURNERS ADDED TO NO. 90 BOILER

In an effort to increase this initial steam temperature, advantage was taken of openings which had been provided originally in the upper part of the furnace of No. 90 boiler for additional coal burners but were never used. Four oil burners were installed here, and these are shown in Fig. 9. It was thought that much higher steam temperatures would result and that the evaporation rate in the furnace walls would be cut down if the oil burners were used at the start rather than normal coal firing. Tests were made using these oil burners alone before a quick start was made and disclosed that a steam temperature of 900 F could be obtained with a steam flow of 220,000 lb per hr.

The results of a typical quick start using the oil burners are shown in Fig. 13. Here the initial steam-chest temperature was allowed to be much higher than had been the usual practice, or

720 F, and the rolling time was cut down to 10 min. The turbine metal temperature drop was from 720 F to 670 F or 50 F, and the rise was 100 F in 23 min and only 150 F in the first hour. As can be seen on the chart the steam temperature at the start was still only about 20 F above saturation, despite the use of the oil burners, and this temperature increased rapidly only after the throttle was opened, rising 105 F in the first 5 min. At the present time an additional by-pass around the turbine is being designed so that the superheater will be cleared of water, and the desired steam temperature will be obtained before opening the throttle. When this is installed the problem of steam-temperature control during starting will have been solved.

Fig. 14 shows the comparison of quick starts with and without the auxiliary front-wall oil burners.

Before closing the subject of quick starts on topping units, it must be emphasized that the rapid machine accelerations advocated in this paper apply only when the metal temperature of the high-pressure sections of the turbine have not fallen below the minimum of the range of the boiler steam-temperature control. In other words, after extended shutdowns the rolling time should be controlled by the time required to bring the temperatures of the high-pressure sections of the turbine up to the minimum steam temperature obtainable from the boiler at the rate of 100 F per hr. It is only when this condition of metal and steam temperature is fulfilled that the unit can be accelerated in approximately the same manner as practiced for quick starts. In the extreme case where a machine has been shut down for such a length of time that all its component parts have reached room temperature, this preheating must be done slowly on account of the large temperature differential existing between the turbine parts and the incoming steam. This initial heating may take several hours.

SHORTENING STARTING TIME ON LOW-PRESSURE CONDENSING UNITS

After the success of quick starts on topping units, consideration was given to shortening starting time on low-pressure condensing units all of which operate at throttle pressures between 400 psi and 200 psi.

A very complete paper⁵ on the subject of short starting of condensing units was reported in 1948, by H. P. Dahlstrand of the Allis Chalmers Company, to the Committee on Power Generation of the Association of Edison Illuminating Companies. In this paper the author summarized the requirements for short starts on condensing units as follows:

- 1 Keeping steam temperature as close to the normal as is practical during the removal of the load until the closing of the throttle valve.
- 2 Having the turning gear in operation during the whole of the shutdown period.
- 3 Maintaining temperatures of the turbine structure as close to shutting-down temperatures as practical until the unit is again started.
- 4 Checking the temperature at the inlet and the exhaust of the turbine structure.
- 5 Temperature of steam from the boiler should be about 100 F above the temperature of the cylinder at the inlet point.
- 6 Condensing equipment should be started before steam is admitted and cooling sprays in exhaust started at the same time.
- 7 Open the throttle valve and bring the turbine up to speed, synchronize, and put 10 to 25 per cent load on. During this time bring the vacuum up as fast as possible. The actual time for this operation should be determined with relation to the increase in steam temperature.
- 8 Increase the load at the specified rate and at the same time maintain the specified rate increase in steam temperature.

Mr. Dahlstrand showed actual starting time on an 80,000-kw reheat unit of 30 min and stated that this starting time was limited by the time required to obtain the necessary vacuum. The author sums up his paper with the sentence, "The starting time after short shutdowns is largely dependent upon the control of inlet steam temperature and vacuum, which means that any starting procedure for a given steam-turbine generating unit must be worked out with full consideration of the boiler and condenser characteristics."

The first Consolidated Edison Company low-pressure condensing

FIG. 15 160,000-KW, 24-STAGE TANDEM-COMPOUND DOUBLE-FLOW STEAM TURBINE, NO. 4 UNIT, EAST RIVER STATION

FIG. 16 METAL TEMPERATURES, $2\frac{1}{2}$ -Hr START, UNIT No. 4FIG. 17 $2\frac{1}{2}$ -Hr START, UNIT No. 4

ing machine on which quick-start trials were made was the No. 4, 160,000-kw, tandem-compound, General Electric unit at East River Station. Fig. 15 shows the location of thermocouples throughout the machine. Note particularly the thermocouples which are located in the path of the steam exhausting from the last wheels of the unit, because, in later illustrations, the temperatures recorded at these points are of considerable interest. In the early history of this machine which was initially operated in September, 1929, before the advent of turning gears, the practice was to take $2\frac{1}{2}$ hr to start, even after an overnight shutdown. While this practice is no longer in vogue since the installation of a turning gear, a test start run was made recently to learn what temperature changes took place throughout the machine during a $2\frac{1}{2}$ -hr start. Fig. 16 shows that, under this early starting method, the rates of temperature changes at the high-pressure end of the unit were very gradual. The sudden increase and decrease in temperature on point 6 while the machine is being loaded after about 10 hr of elapsed time is due to the high-pres-

sure gland leak-off being connected to the bleed piping at a point between the 21st stage bleed in the cylinder and the bleed valve. This sudden rise in temperature is due, therefore, to the pressure building up in the high-pressure packing as load increases on the machine and hot steam flowing from the packing into the bleed belt with the bleed-valve shut off. The sudden drop occurs when the bleed valve is opened, and the leak-off steam is diverted to the heater.

The shutdown indicated in the rolling period in Fig. 16 was a part of the Consolidated Edison procedure to preheat some of its generator fields before bringing these machines up to speed. During the brief shutdown period, the centrifugal force which locks the field coils is relieved and these coils are permitted to expand freely to their desired length. This has the double advantage of eliminating the possibility of stressing the coil material beyond its elastic limit in the coil sections embedded in the field slots and of reducing field end-turn distortion. Recently this procedure was changed on this machine, and the present

FIG. 18 (left) METAL TEMPERATURES, $1\frac{1}{2}$ -HR START, UNIT NO. 4

FIG. 19 (left) $1\frac{1}{2}$ -HR START, UNIT NO. 4

practice consists of doing all the preheating while the unit is on turning gear before starting.

Fig. 17 shows the extreme temperature changes which occurred during the starting cycle under the original starting procedure, due to the low vacuum and the reheating of the steam in the exhaust by windage from the large exhaust wheels, which on this machine have a tip speed of 1015 fps. In the early days it was the practice to build up the vacuum slowly as shown by the vacuum curve. Note the two sudden decreases in vacuum when steam is admitted to the turbine. As the spindle accelerates, observe that the temperature of steam entering the condenser rises rapidly, reaches a temperature corresponding to condenser vacuum, and then begins to be reheated, finally reaching a maximum temperature of 340 F. The temperature of the exhaust

steam $1\frac{1}{2}$ in. away from the last stage wheels reaches approximately a maximum of 390 F. These maximum temperatures are followed by very sudden decreases in temperature at a rate of about 800 F per hr as the vacuum is rapidly established, after the machine has been synchronized and sufficient steam flow passes through the turbine to cool the buckets. With this rapid cooling it is surprising that no casing cracking had been experienced under the induced thermal stresses, when considering that the exhaust shells are made of thin cast-iron sections and very heavy flanges. Perhaps modern-day limitations of 100 F temperature change per hr as suggested by some manufacturers are overconservative.

After a turning gear was installed on No. 4 at East River in November, 1939, to keep the spindle turning during shutdown

FIG. 18 (right)

FIG. 21 45-MIN START, UNIT NO. 4

FIG. 22 METAL TEMPERATURES, 30-MIN START, UNIT NO. 4

and assure a minimum eccentricity at time of start, the starting time was reduced to $1\frac{1}{2}$ hr. Fig. 18 shows the high-pressure-cylinder temperature changes during this shorter start. Note the same occurrence of a sharp rise and fall in the bleed-belt temperature as reviewed in the figures covering the $2\frac{1}{2}$ -hr start. Points 2 and 3 show a somewhat more rapid rise in temperature at the high-pressure end of the machine than in the $2\frac{1}{2}$ -hr start, due to more rapid loading for a short period.

Fig. 19 shows the exhaust-end condition for the $1\frac{1}{2}$ -hr start. Again, note the reheating of the steam, which reaches a maximum of 365 F with the machine at full speed just prior to loading. As in the case of the $2\frac{1}{2}$ -hr start, there is cooling of the exhaust end at the high rate of 800 F per hr.

Fig. 20 shows the temperature changes which take place in the high-pressure element during a $\frac{3}{4}$ -hr start to be quite gradual. Note that point 6 shows no sudden rise and fall in temperature as in the case of the $2\frac{1}{2}$ -hr and $1\frac{1}{2}$ -hr starts, owing to the bleed heater being in service during all of the rolling and loading period.

Fig. 21 shows the temperature and vacuum changes at the exhaust end of the unit. The exhaust temperature again rises and falls rapidly but takes place during a shorter time interval. However, it is to be noted that the peak temperature reached is approximately 30 to 40 F lower than in the case of the $2\frac{1}{2}$ -hr start.

Fig. 22 shows the temperature changes in the high-pressure cylinder during a $\frac{1}{2}$ -hr start. Again, there are no excessive

rates of temperature change in the high-pressure end of the machine. Note the sharp rise in temperature of point 6 on the 21st stage bleed belt while the companion point 7 remains relatively constant. During this start, the 21st-stage heater was out of commission for repairs, and the high-pressure packing leak-off is reheating the steam in the 21st-stage bleed belt. Consideration is being given to making supplementary piping connections so that this uneven temperature condition in the low-pressure cylinder can be avoided.

Fig. 23 shows the low-pressure-end conditions during this half-hour quick start and, again, there is the pronounced rise and fall in temperature of the last-stage buckets.

Fig. 24 shows a comparison of the exhaust-end heating and cooling characteristics during all of the starts, and the gradual falling of the peak temperatures at the last-stage buckets as the starting time is shortened.

CONCLUSION

It has been calculated that if quick-starting could be reduced to 15 min or less on all topping and condensing machines on the Consolidated Edison System, an annual saving of approximately \$250,000 would result. This saving is made up of auxiliary power, stack and river losses, and fuel fed to the furnaces.

In addition to the operating saving just mentioned, there are many practical operating advantages which result from quick-starting. A notable instance occurred, on August 27, 1948, when the Manhattan Cooper Square network was de-energized because of failures of simultaneous outages in Waterside No. 2 of the four topping units in this station. As soon as the first generator cables were temporarily repaired on unit No. 4, this machine was brought up to speed and was generating power in less than 15 min, and the network re-energized. If the old original 3-hr start had still been in vogue at the time, the network would have remained out of service at least 2 1/4 hr longer.

On April 18, 1949, with simultaneous forced outages of the two topping units at Sherman Creek, No. 9 unit was restored to service in 22 min, after having been shut down for 11 hr.

To a certain extent, the short starting time relieves the problem on the turbine-room floor of each station in the early morning.

At that time it is customary to have two or three machines in the process of slow rolling preparatory to their going on load. With the quick-starting technique perfected it would be possible to put machines in service one after the other. Fewer men could

FIG. 23 30-MIN START, UNIT NO. 4

FIG. 24 TEMPERATURE OF STEAM LEAVING LAST LOW-PRESSURE WHEELS, UNIT NO. 4

focus their main attention on only one machine, instead of several.

It is fully expected that the starts discussed in this paper ultimately will be reduced to 5 min or less and will be followed by faster rates of loading in the first few minutes, thus reducing the heating and cooling of the exhaust ends. Work is now in progress on quick-starting of all the various types of condensing machines on the system.

Supplement⁶

As stated in the previous papers,⁶ the principle of the quick-start procedure is simple, and consists of admitting steam into a turbine at a temperature equal to or higher than the metal temperature of the heavy section of the machine. The purpose of matching these temperatures is to eliminate or minimize practically all of the thermal shock coincident with the start of a turbine generator. The degree of success obtained in this direction is shown in Fig. 25 of this supplement, in which the data for quick starts, transposed from Figs. 3 and 5 of the paper, are compared with the most recent data obtained on units Nos. 6 and 7 at Waterside Station. It can be seen that with experience and better co-ordination of sequential operations during the start, an even closer matching of the temperatures of the incoming steam and of the turbine shell is now realized.

The first 15-min quick start was made on No. 4 Westinghouse topping unit at Waterside on June 25, 1946. Since that time

⁶ The original paper on quick starting of boilers and turbines was delivered before the ASME Semi-Annual Meeting, Chicago, Ill., June, 1947, as paper No. 47-SA-18. (See Trans. ASME, vol. 70, 1948, pp. 201-209.) A second paper, which was a review of the progress made since the first one was written, was presented at an ASME Metropolitan Section Meeting in May, 1949, and again at the 1950 ASME Spring Meeting, as paper No. 50-S-1. The material contained in the supplement was not available for inclusion in the preprint for the 1950 ASME Spring Meeting and has been added in the final publication.

and up to March 15, 1950, over 1000 quick starts as shown in Table 1 have been performed without the slightest indication of trouble.

^a In addition to the 15-min starts listed for units Nos. 1 and 2 at East River Station, there have been 617 and 552 30-min starts, respectively, since July 17, 1947.

FIG. 25 COMPARISON OF QUICK STARTS AS PRACTICED IN 1949 AND 1950 AT WATERSIDE STATION

Since the 1947 paper,⁶ ten machines have been added to the list of those on routine of quick starting after overnight shut-downs. All of the units listed are started in 15 min with the exception of No. 4 tandem-compound 160,000-kw condensing unit at East River Station which is now started in 20 min. Reducing the quick-start time of this large tandem-compound unit from the 30 min, as given in the present paper, has still further improved its starting-up operation.

The decision to shorten the rolling period of a unit is not taken arbitrarily. On the contrary, data including the shell-metal temperature gradient, expansion, vacuum, and the operator's observations on the normal long-roll start are first carefully studied. If there is nothing in the data that shows it would be detrimental to shorten the starting time, instructions are issued to make the next start in 10 to 15 min less. Again, the record of the shorter start is analyzed and a second shortening of time is made. This procedure is repeated until the time is finally reduced to 15 min.

We limit the starting time to 15 min because it is felt this is the minimum which still gives the operator a comfortable period to observe the machine as it accelerates. Fundamentally, in so far as the unit is concerned, it is believed that it could be accelerated as fast as dry steam can be supplied to it.

The first application of the quick-start procedure on one of our cross-compound machines was made on No. 6 Westinghouse, 110,000-kw, 425-psi, 725 F condensing unit at Hudson Avenue early in 1950. Fig. 26 shows a cross section of each element together with the location of the test thermocouples. The machine receives its steam from a common header system, which is an ideal arrangement for quick starting because the steam temperature at the start is at all times above that of the metal parts of the front end of the high-pressure turbine, assuming, of course, that one or more boilers are operated in the station throughout the night. The high-pressure element of this unit is also well suited for quick starting because of its double-shell construction. In this type of machine only the nozzle block or steam bowl is exposed to high temperatures during starting. The main cylinder structure

FIG. 26 110-MW CROSS-COMPOUND WESTINGHOUSE UNIT NO. 6, HUDSON AVENUE STATION
(1800 rpm, 400 psi, 730 F.)

is in contact with steam which is at a relatively low temperature after having expanded through the impulse section. Hence the temperature of the governor end of the high-pressure cylinder, as indicated by points 3, 4, 5, and 6 in Fig. 27, shows no appreciable change in the long slow roll period so that nothing is being accomplished in so far as expansion or contraction of the high-pressure cylinder is concerned. Points 11, 12, 13, and 14, the former two in the exhaust shell and the latter two in the steam path immediately adjacent to the exhaust of the last-stage wheel, indicate peak temperatures in the metal of 195 F and in the steam path of 335 F.

Fig. 28, which shows the comparative temperature conditions during the 15-min quick start, indicates even less change in high-pressure shell temperatures than occurred during the long slow roll, and the peak temperatures previously referred to in the low-pressure element have been lowered to 165 F and 290 F, respectively.

While the common header system lends itself to quick starting by delivering steam which is always hotter than the turbine shells, such is not the case on unit systems because the steam tempera-

ture leaving the superheater of our unit boilers is always lower than desired until sufficient mass gas flow and gas temperature can be attained at the superheater. In this respect it is well to remark here that one of the fallacies in the thinking of many operators is that little or no metal stress develops in the turbine when the unit is started immediately after an accidental shutdown. Test has demonstrated that even after a shutdown of a few minutes, the turbine temperature may be several hundred degrees hotter than the entering steam on restarting. Under this condition the turbine spindle with its higher rate of heat transfer cools off faster than the turbine shell, and a possible forward axial rub may result.

By the summer of 1950 we shall have installed on all of our single-boiler single-turbine topping units, turbine by-passes so that steam will be introduced into the turbine only when it reaches a temperature 50 F to 100 F hotter than the turbine shell. This design feature, besides taking care of the temperature relation on quick starting, will also handle the operating condition of restarting immediately after a brief outage of a few minutes.

pany and V. S. Renton of the Public Service Electric and Gas Company of New Jersey presented⁷ the results of extensive tests made on a new 100,000-kw condensing unit installed in the Essex Station of the Public Service Company of New Jersey. It has been encouraging to find in the authors' discussion a confirmation of our belief that the quick-starting procedure imposes less strain on the turbine structure than does the starting method commonly practiced in the industry today. It is our hope that tests of this sort by other operators, as well as the endorsement given by Mr. Dahlstrand of the Allis-Chalmers Manufacturing

Company, will add to the present knowledge of quick starting and faster loading of turbines.

QUICK STARTING OF TURBINES AFTER WEEK-END SHUTDOWN

All of the turbine quick-starting investigations which we have made to date and reported in our previous papers⁴ have been based on starts after overnight shutdowns.

Recently, after a week-end shutdown we had an opportunity to observe the changes which occurred in No. 9 turbine at Waterside while quick-starting its boiler.

Fig. 29 shows a cross section of this 50,000-kw, 1600-psi, 950-F Westinghouse topping turbine, together with the locations of the thermocouples used during this quick start from cold test.

Fig. 31 shows the turbine metal temperatures, pressures, speed, and differential-expansion readings obtained. Relatively low rates of metal-temperature rise occurred in the turbine metal structure during the rolling period. However, as the load was increased at the rate of 1 mw per min above 13,000 mw, the impulse chamber pressure and temperature rose very rapidly; the latter temperature, represented by point No. 9, increased at the rate of 450 F per hr. Point No. 8, located on the outer skin of the massive horizontal flange of the main cylinder joint in line axially with point No. 9 in the impulse chamber, shows an extreme temperature lag. Very high compression stresses occur at the inner main-joint surfaces as the result of this marked temperature gradient across the joint face, and the manufacturer is studying the problem.

The differential-expansion curve shows that the axial clearances between the cylinder and spindle increased by only 50 mils during the rolling period. As the unit was loaded, the exhaust-end temperature dropped rapidly, causing the clearances to reduce gradually toward the normal running values.

SHUTTING DOWN AND STARTING OF HIGH-PRESSURE BOILERS

Now that we have the turbine and boiler procedure for quick starting after overnight shutdown satisfactorily solved, we are looking into the problem of starting boilers and turbines after shutdowns when the boiler pressure is reduced either to zero or to a very low value. This boiler-starting condition is entirely dif-

⁷ "Operating Characteristics of the 100,000-Kw Essex Turbine Generator," by Stanford Neal and V. S. Renton, Trans. ASME, vol. 72, 1950, p. 267.

3600 RPM-1600 PSI-950 °F

FIG. 29 50,000-Kw WESTINGHOUSE TOPPING UNIT No. 9, WATERSIDE STATION
(3600 rpm, 1600 psi, 950 °F.)

ferent from that of a boiler which has been bottled up near operating pressure for an overnight shutdown. In this latter case the boiler is brought up in only a few minutes more than the 15 min required for the turbine.

We have always felt that the present starting time from the cold condition, as recommended by the manufacturers of boilers, is much too long to fit into our operating cycle. Therefore we have made studies to determine temperature changes which occur in high-pressure boilers during such cycles and for that purpose installed thermocouples as shown in Fig. 30, on Waterside No. 90 Combustion boiler which is designed for 1,000,000 lb of steam per hr at 1800 psi and 950 F.

From the data obtained it was observed that during an overnight shutdown of No. 90 boiler when the drum pressure was purposely allowed to fall to 300 psi, a large temperature differential occurred between the top and bottom of the boiler-drum metal. In Fig. 32, which represents one of these tests, it will be noted that this differential attained 130 F for the 60-in. drum and 50 F for the 54-in. drum.

On another shutdown prior to a 3-day outage for boiler repair, during which the cooling of the boiler was accelerated by running the induced-draft fans, a spread of 170 F was noted in the metal temperatures at the top and bottom of the 60-in. drum.

However, in all our tests it was consistently observed that no appreciable drum-metal temperature differential was created during the starts of No. 90 boiler.

After reviewing these observations, the manufacturers indicated more concern about the drum stresses in shutting down than in those which might be induced by a proposed faster-starting cycle. They also agreed with our opinion that the reason the bottom of

the 60-in. drum was cooling faster than the top was due to the introduction of feedwater which is cooler by several hundred degrees than the on-line feed temperature after the mills were out out, due to loss of heat from the economizer and the turbine bleed heaters. To reduce this metal difference between the top and bottom of the drum to less than the manufacturer's recommended 100 F, it is now the practice to fill the drum immediately after firing ceases.

With the assurance that only minor drum-metal temperature differences exist in a normal start, as shown in Fig. 32, it was then decided to quick-start No. 90 boiler which had cooled to room temperature after a 3-day outage. This decision was reached after further reasoning that:

(a) There was no likelihood of rolled joint leakage in starting because the thin wall tubes expand faster than the heavier header and drum walls.

(b) There was no danger of superheater elements overheating because the nondrainable superheater tubes trap water which acts as a cushion by evaporation and keeps the superheater tubes cool during the initial period of the start.

The first quick-start test was run on February 5, 1950, and the starting time from cold was reduced from 7 hr to 3½ hr. Fig. 33 shows the pressures and temperatures obtained during this quick start.

In this test, normal firing rate was increased on the basis of raising the drum pressure at a rate that would increase saturation temperature at approximately 150 F per hr. As can be seen from Fig. 33, the maximum drum-metal temperature differential never exceeded 35 F. The superheater-metal temperatures did not reach excessive values and, as a matter of fact, the tem-

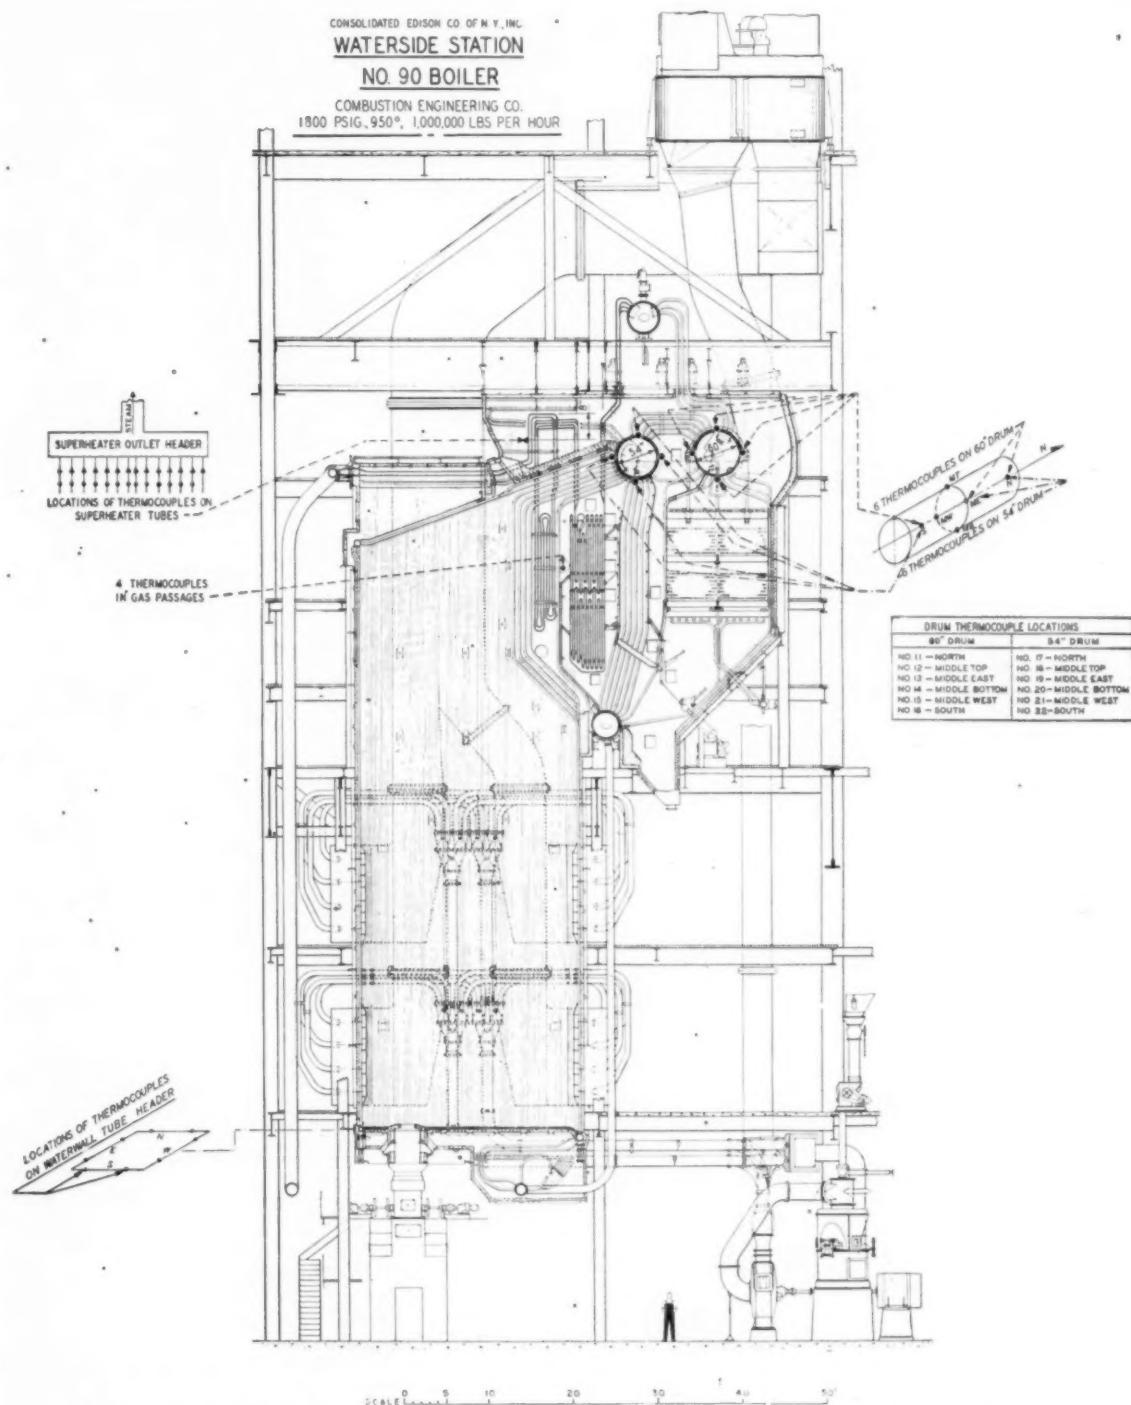

FIG. 30 1800-PSIG, 950-F, 1,000,000-LB-PER-HR NO. 90 COMBUSTION-ENGINEERING BOILER AT WATERSIDE STATION

FIG. 31 ONE-HOUR START AFTER SHUTDOWN OF 44 Hr. No. 9 TURBINE GENERATOR AT WATERSIDE STATION

peratures of the hot gases (not shown on the illustration) surrounding the superheater tubes were found to average 850 F which is lower than anticipated and within safe values.

After every stop and start we are obtaining new information that leads us to believe that boilers can be started from cold much more rapidly than has been the practice in the past, and more rapidly than is at present recommended by the boiler manufacturers. We believe the quicker starts impose no greater strain in the boiler structure than the slower starts.

A potential cause of boiler extended outages ever-present in our system is due to the frequent shutting down of high-pressure units at night. As a result of these repeated shutdowns, leakages occasionally occur at the tube rolled joints in the bottom-wall header. We feel that this type of trouble could well be eliminated on new boilers by welding stub-end tubes into the header at the factory. The number of header handholes would thereby be decreased by 75 to 85 per cent and would greatly reduce the possibility of gasket leaks. This is of importance to us because one leak may cause the outage of a 1,000,000-lb-per-hr boiler for 24 to 36 hr. Additional original shop or field construction, if any, to obtain welded stub design, therefore, would amply pay for itself by preventing a few outages.

CONCLUSION

The conclusion in the present paper enumerates the benefits

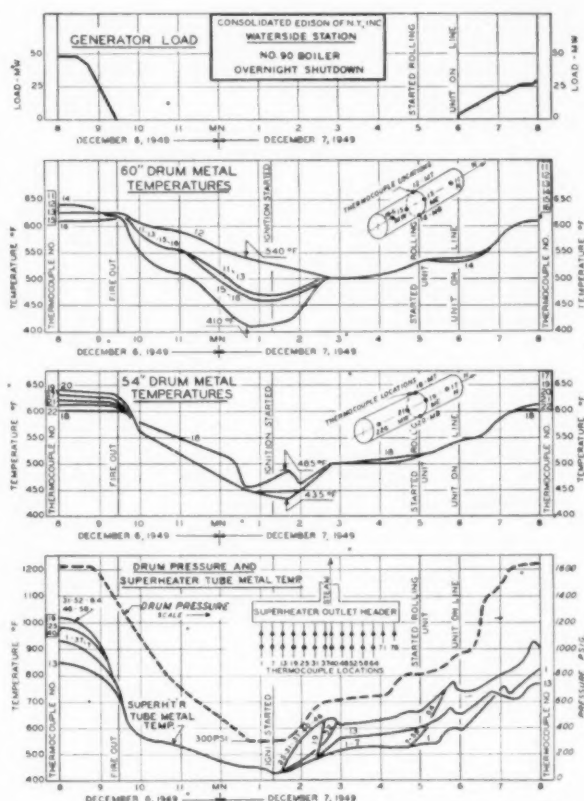

FIG. 32 OVERNIGHT SHUTDOWN, No. 90 BOILER AT WATERSIDE STATION

accruing to the Consolidated Edison System as the result of quick starting after overnight shutdowns.

There now can be added to these the time gain of 3 to 4 hr on every occasion that a high-pressure boiler is removed from service and its pressure relieved for inspection and maintenance.

Our investigation of reducing the starting time of boilers from a cold condition has been conducted for a relatively short period, but we have every reason to believe that starting can be done at a much faster rate than that now advocated by the manufacturer.

Discussion

A. A. CASEY.⁸ On the topping turbines at Waterside and Sherman Creek Stations the temperature-control problem appears to be at the head end where there was rapid cooling of the steam-chest metal by the steam admitted for rolling, and subsequent heating of the metal as the speed was increased and load was applied. In contrast, on the condensing turbine reported on at East River Station, there was little change in metal temperature at the head end during the rolling period. The problem of control of temperatures on this turbine appears to be at the exhaust end where the steam leaving the last row of blades was reheated by friction from the large exhaust wheels. As pointed out by the authors, steam leaving the last row of blades is reheated during the quick-starting, but the peak temperature is

FIG. 33 3 $\frac{1}{2}$ -HR START, NO. 90 BOILER AT WATERSIDE STATION
(February 5, 1950.)

lower, and the time interval is shorter. As a result, there is less heating of metal at the exhaust end.

Of special interest is the effect of the number and size of boilers supplying the steam for starting. Low steam temperature at Sherman Creek with one boiler per turbine presented a different problem from Waterside with two boilers of smaller size per turbine. In addition, the use of oil burners at Sherman Creek and the comments on steam condensation in the pendant-type superheater emphasizes that boiler characteristics must be taken into account in developing quick-starting procedures. It would be interesting to know what the boiler-drum and superheater metal temperatures were during the quick starts.

The calculated annual savings possible with quick starting is \$250,000. Was this calculation based on operating data taken during normal and quick starts? A division of this total into the various costs would be informative.

The recent Prime Movers Committee report on Turbines, Condensers, Auxiliaries, etc., for 1946-1947 in the section on statements by operating companies shows that, in addition to Consolidated Edison Company of New York, some quick starting is used or is being tested by the following: Pennsylvania Power and Light Company; Public Service Electric and Gas Company; Wisconsin Electric Power Company.

B. J. Cross.⁹ A rate of increase in pressure, corresponding to a temperature rise of not greater than 100 F per hr has been the recommendation of boiler manufacturers in bringing a boiler in service. Actually, the concern is not so much the rate of temperature rise as the uniformity of temperature throughout the boiler as it is brought up to operating pressure.

This 100 F per hr rate is set as a safe figure that would not be expected to result in temperature differences which would produce undesirable stresses in the boiler parts, and particularly in the drum structure. It is admittedly an arbitrary figure and in the absence of reliable information was set to provide a safe margin in consideration of differences in design and operating conditions.

The observance of this limit of temperature rise would require a minimum of about 5 hr to bring a high-pressure boiler in service from a cold condition.

When boilers are taken out of service only infrequently, this time limit does not affect the operating economy of a station seriously. In fact, a similar time limit has also applied to turbines.

With a load pattern such as that of the Consolidated Edison Company, it is highly desirable that the time period be reduced. As pointed out by the authors of this paper, a substantial saving in operating expense may be effected and also by the advantage of quicker availability an improvement in customer service will result.

The greatest difference in drum temperatures occurs during the shutdown period. The cause of these large differences has been determined and corrective measures taken. In putting a boiler in service at successively shorter periods, no difficulties have developed, and a case may possibly be made for an improvement in conditions at the shorter periods.

In the start-up after a short or overnight shutdown, the critical factor is steam temperature. A supply of steam at or above the temperature of the turbine steam chest is required. Actually, this degree of superheat is required before there is any flow of steam. This dilemma will be solved by the provision of the turbine by-pass.

While the protection of the superheater elements from overheating has not proved any great problem, the turbine by-pass also will provide favorable conditions for the superheater and will permit firing rates necessary to produce the early superheat required.

The problem of leaks in rolled-tube joints and handhole-plate seats may be eliminated by the welding procedure suggested by the authors or, less expensively, by seal-welding rolled joints and handhole plates. Both techniques have been developed and used.

The authors of this paper and their co-workers are to be highly commended on their very thorough study of this problem. The progress reported in this and previous papers represents many years of hard work and intensive and systematic study.

The information they have made available will be of great value to the whole industry. Even with what may be termed a normal load pattern of a public-utility station, there are still many advantages in the quick-start procedure that has been developed. One of the major items of expense in maintenance is the loss of service of the equipment, and a few hours gained at each shutdown represents a worth-while yearly saving.

In their final conclusion the authors state that they believe the starting of boilers may be done at a much faster rate than that advocated by the manufacturer.

The writer believes that the industry will agree with that conclusion. However, because of differences in design and arrangement and also variation in operating conditions, the details of

⁹ Manager, Development and Research Division, Combustion Engineering-Superheater, Inc., New York, N. Y. Mem. ASME.

procedure in coming-off and going-on load may be different for each boiler. We would strongly recommend that the minimum starting period and the safe procedure for both shutting down and starting up be established by a program of temperature measurement such as the authors have described.

H. P. DAHLSTRAND.¹⁰ In this paper the authors have reported further studies of this vital question first reported by J. C. Falkner, R. S. Williams, and R. H. Hare in 1947. It is indeed gratifying, and the authors should be congratulated for proving the soundness of their ideas in developing a practical method for the control of the various conditions which will in all cases result in maximum reliability and economy of the equipment during the starting period.

In commenting on the original paper the writer fully agreed with the authors on the conclusions reached. The first paper covered large topping turbines only, whereas the present paper includes condensing units as well. In both cases the problem is the same, except that the control of vacuum in the latter case becomes of considerable importance in determining the length of the starting period.

Of special interest is the addition of auxiliary oil burners in the boilers for raising the steam-inlet temperature closer to the metal temperature, as well as the proposed by-pass around the turbine for draining the superheater of water. It indicates that an exhaustive study has been made in order to obtain the ideal condition which not only will shorten the starting period but also, which is more important, will add greatly to the reliability of the steam-turbine units because of the decrease in differences between the steam and metal temperatures. This will be of greater importance as higher temperatures are adopted using materials with larger coefficient of expansion and lower heat conductivity.

Commenting on the quick starting of a large condensing unit, it is shown that the shorter the starting period the lower will be the exhaust-steam temperature. There is naturally a certain limit depending upon how quickly full vacuum is established. In reducing the starting time from $2\frac{1}{2}$ hr to 45 min, the exhaust-steam temperature was materially reduced. The question might be asked, "If full vacuum had been obtained at the start of the rolling period, what would the exhaust-steam temperature have been?" It is important that this temperature does not exceed a certain limit, as stresses in the last row are higher than in any other blades of the unit. There is also the danger of loosening the blades in the grooves and breakage of shroud and lacings due to expansion of the blade structure.

All large steam-turbine units, 1800 rpm and 3600 rpm, built by our company in the past several years have been provided with steam-sealed glands only. With this type of gland, it is possible to obtain full vacuum in the condenser with the unit operating at turning-gear speed. The advantage of this type of gland has been mentioned previously.¹¹ It will also result in much lower exhaust temperature during the starting period, as indicated in the curves, Fig. 34, herewith. These curves show the conditions during the starting period when the unit is started from cold. The tip speed of the last row of blades is 1140 fps. Starting time for a cold unit is limited by how fast the various parts absorb the heat without excessive distortions, whereas units with short shutdowns, in which the metal temperature of the high-pressure elements approach that of the operating temperature, can be started relatively quickly, provided the steam-inlet temperature approaches the metal temperature and a high vacuum is obtained in

¹⁰ Director of Steam Turbine Engineering, Steam Turbine Department, Allis-Chalmers Manufacturing Company, Milwaukee, Wis. Fellow ASME.

FIG. 34 CONDITIONS DURING START-UP OF 80,000-Kw 1800-Rpm REHEAT UNIT

the condenser to prevent excessive heating of the last rows of blades. In the curves shown, Fig. 34, the vacuum in the condenser is 21 in. at the start of the rolling period, resulting in a maximum exhaust-steam temperature of 170 F. This temperature would have been considerably lower if a vacuum of 29 in. had existed. Therefore, to shorten the starting period of a condensing unit after a short shutdown, both the control of the steam-inlet temperature and the vacuum is of vital importance.

W. R. LA MOTTE.¹² For years it has been the practice among conservative operators of turbine generators to require long rolling periods to "gradually warm up the machine." If a particular unit appeared to start rough, then the invariable answer was to start even more slowly.

The work at Consolidated Edison is particularly valuable for it is an effort to put the starting procedure on a rational basis and to provide the operator with a clear measure of what he is accomplishing.

Quite naturally, the writer's company is interested and has done some work along these lines, as reported in a paper by Neal and Renton.⁷

The writer would like to report on another matter, however, which may be helpful to other operators who may be contemplating experimental work on their own turbines. Last spring, when a 125,000-kw, 1250-psi, 950-F, cross-compound turbine was opened, the horizontal joint was found to be out of true and many

man-hours of labor were required to bring it back into shape. During the outage, 32 thermocouples were installed on the high-pressure cylinder and steam chests. These showed clearly that opening of the secondary and tertiary valves increased the temperature at the inner edge of the horizontal joint much more rapidly than at the outer edge or the bolts. As a result, there is a time during the loading cycle when the temperature difference across the flange is 250 to 300 F. The inner edge of the joint is crushed and there is eventual leakage.

A remedy suggested by the manufacturer is installation of a manifold through which live steam may be admitted to the annular space around each main flange bolt, thus keeping the bolts and outer portion of the flange up to temperature. Such a manifold is being built but is not yet installed, hence a report on its effectiveness cannot be made at this time.

This is brought to the authors' attention with the suggestion that the horizontal joint be included in the thermocouple installation.

R. L. REYNOLDS.¹³ Of particular importance are the discussions in this paper of the following additional aspects of the quick-starting problem which were not covered in the previous presentation:⁸

(a) Inspection of a superposed unit after having been subjected to several "quick starts."

(b) Application of the quick-start method of operation to a turbine supplied by a single boiler.

(c) Application of the quick-start method to a condensing-type turbine.

From a turbine-engineer's point of view, the determination of the proper starting cycle depends primarily upon the following conditions:

- (a) Change in axial and radial clearances between stationary and rotating parts, particularly blades and sealing strips.
- (b) Stress in bolts and flanges.
- (c) Ability of boiler to follow changes in turbine steam demand.

Inspection of one of the Waterside superposed turbines, after several quick starts and, in addition, several water and caustic washing cycles, shows that the use of this method of starting has caused no distress to the turbine. Therefore this method appears to be fundamentally sound and worthy of continued study and application.

In order to obtain more information on the effect of starting and loading units, we have installed thermocouples in the flange and bolts on a turbine quite similar to the Waterside No. 6 unit referred to in the paper.

Readings taken on these thermocouples during a start, where full-temperature steam was used for heating, indicate that in the throttle valve, where the steam sweeps past the inner wall surface at fairly high velocity, and where the covers are bolted to the body with studs, the metal temperatures in the flange and bolt follow each other quite closely and build up to nearly the steam temperature quite rapidly. In the steam chest, the flange and bolt temperatures do not build up quite so rapidly but do follow each other quite closely.

However, in the main turbine cylinder where the steam remains stagnant in some chambers during the starting cycle, the metal temperatures respond much more slowly. Of even greater importance is the fact that the temperature differential between the flange and bolt becomes quite large. This large differential re-

¹² General Superintendent of Generation, Public Service Electric and Gas Company, Newark, N. J. Mem. ASME.

¹³ Manager, Central Station Turbine Section, Westinghouse Electric Corporation, South Philadelphia Works, South Philadelphia, Pa. Mem. ASME.

sults in high compressive stresses at the sealing surfaces of the flange joint and in high tensile stresses in the bolt.

Part of this differential is probably due to the type of bolt used, this being the through-type with clearance space between the bolt and flange. With this type of bolt, heat is conducted from the flange to the bolt through the seating surface of the nut and thence through the nut into the bolt along the thread engagement. This means that heat is transmitted from the flange to the bolt along only a comparatively short length of the bolt, except for the relatively slow radiation of heat across the clearance space between the flange and bolt.

These measurements dictate the need for further study of this problem to devise means for making the bolt temperature and expansion conform more nearly to flange temperature and expansion. As an approach to this problem, means can be provided to circulate steam through the clearance space around the bolts or to coat the bolts with some material to increase heat emissivity.

During the opposite cycle of shutting down or reducing load, the flange will tend to cool at a faster rate than the bolt, thus causing the bolt tensile stress and the flange compressive stress to decrease. This reduction in stress is not harmful to the bolt and flange material but, if the temperature differential becomes great enough, it will cause the joint to leak steam. This is naturally objectionable but will not damage the joint surface, provided the leak occurs in the high-temperature region where the superheat of the steam is in excess of 100 F.

From the standpoint of blade and seal strip clearances, these must be determined on each installation to insure against rubs between stationary and rotating parts during the starting cycle. During the shutdown period the rotor is kept straight by rolling with the turning gear. However, the stationary casing tends to "hump" because of the upper half cooling off at a slower rate than the lower half. As a result, radial clearances at the bottom become smaller, and provision must be made to make these clearances sufficiently large to avoid rubs. Also, starting procedure should be arranged to straighten the casing to reduce the possibility of these radial rubs.

Axial clearances also must be determined during the starting and loading cycles to avoid rubs. The paper describes means for doing this and inspection showed that no axial rubs of any consequence had occurred.

The time required to bring a unit up to speed after a shutdown depends primarily on the following conditions:

- (a) Length of shutdown period.
- (b) Temperature of steam used for starting.

The length of shutdown will determine, to a great extent, the temperature of the metal in the throttle valve, steam chest, and turbine casing. It also will affect, to some extent, the amount of cylinder "humping" due to unequal cooling of the top and bottom halves.

As the authors have pointed out, the temperature of the steam used for rolling the unit should be only slightly higher than the metal temperature. In order to do this at times it may be necessary to make special provisions in the boiler to control the steam temperature as required.

While sufficient information is not yet available to make definite recommendations, we do know that the starting time should not be set at some fixed value, such as 15 min, under all conditions, but will be influenced by the length of shutdown and by the relation of the steam temperature to the metal temperature.

While the 15-min cycle appears to have been satisfactory for overnight shutdowns, where steam temperatures could be maintained at from 50 to 100 F above metal temperature, the safe time after a longer shutdown, where steam temperature cannot be so controlled, should be considerably more than 15 min.

Regarding the question of controlling throttle temperature

during the load-reduction and shutdown period, it has been the practice of some operating companies to reduce throttle steam temperature before starting to remove load. This accentuates the drop in turbine-stage temperatures and, therefore, may produce more severe starting conditions than if the throttle temperature could be maintained at a higher level during the load-removal period. Determination of the method of shutting down will depend upon the means for controlling steam temperature during the subsequent starting cycle. With the unit system, where the steam temperature is usually considerably lower than the metal temperature, a reduction in steam temperature during the shutdown cycle is advisable. However, if a header system is used, which is kept hot because of supplying a substantial steam flow to other units, it appears desirable not to permit the turbine to cool off more than necessary during the shutdown period. In fact, if means could be provided to increase, rather than decrease, initial steam temperatures while load is being removed, the stage temperature drop will be minimized, and the effect on metal temperature will be comparatively small. The turbine will thus be better suited to a quick start with high-temperature steam.

On condensing turbines, the problem of exhaust temperature during the starting cycle may become quite serious. Because of this, it appears advisable to maintain as high a vacuum as practicable during this starting period. In many cases, steam seals can be used to seal the glands at speeds too low for effective water sealing. The quick start helps to keep this exhaust temperature within desirable limits and thus should be beneficial in the low-pressure end of the turbine.

In conclusion, we feel that the authors have made a worth-while contribution in their studies and experiments on the starting phase of operation. Unquestionably, this not only will lead to a substantial saving in time and expense but also will subject the turbine to less severe treatment than when following the somewhat arbitrary rules applied in the past. While this has not been too important during the past few years, when it has been necessary to operate almost continuously at heavy loads to meet the load demand, the time is coming when economical operation will necessitate week-end and, in many cases, overnight shutdowns. This method of operation demands that units be returned to active service in the shortest possible time consistent with proper treatment of station equipment.

C. U. SAVOYE.¹⁴ The limitation of 100 F per hr metal-temperature change has been given, in power-plant operation, an authority which cannot be upheld. Some of us in the boiler business are responsible in a measure for this illicit development, so it seems necessary to explain our contribution and to clarify the original intent.

In the late 1930's the writer's company built its first 2200-psi boiler for an industrial power plant. The drum plate in the heaviest section was 8 5/8 in. thick. Concern over metal-temperature differentials during the starting-up and the shutting-down periods led us to the installation of thermocouples in the drum sheet at four depths. The data obtained during the early operations showed temperature differentials between the outside and the inside of the sheet to be approximately 60 F for a rise in saturation temperature of 200 F per hr, and 18 F for a rise in saturation temperature of 20 F per hr.

Consideration of these results, together with data obtained on thinner drums, led us to the following conclusions:

- 1 If each part of a drum of any thickness is held to within 100 F of any other part, the maximum stress in the drum will remain within the allowable limits.

¹⁴ Executive Assistant, Babcock & Wilcox Company, New York, N. Y. Mem. ASME.

2 With a given drum there is a loose relationship between its rate of temperature rise during starting-up and the temperature differentials between one and another parts of the drum. Past practice indicated that no overstressing of drums up to 4 in. thick was experienced when the starting-up time was extended to at least 4 hr, or to a rise in saturation temperature of approximately 100 F per hr. This 100 deg is an entirely different one from the 100-deg differential between two parts of a drum sheet. Its use as a starting-up "rate" was quite attractive, because it paralleled, roughly, the allowable limit of heat application to superheater tubes before full steam flow through them was established.

3 A high rate of temperature rise during starting-up does not dictate a high stress—unless the rate is continued long enough to produce high differentials in the metal.

For instance, a 600-deg per hr rise for 1 hr could produce a metal temperature differential of 600 F and, therefore, a damaging stress. The same 600-deg per hr rise for 10 min, however, could produce no more than 100 deg metal-temperature differential, and therefore the stress could be acceptable.

4 A starting-up rate of 100 F per hr saturation-temperature rise appeared to be good practice for the predominance of plants where the many advantages in this conservatism would not be counteracted by costly losses because of wasted time. Where rates exceeding 100 F per hr became attractive from an economic standpoint, drum-metal temperature differentials, as registered by thermocouples, were expected to be used as guides in establishing the new rates.

Suggested operating instructions issued later recommended the 100 F saturation-temperature starting-up rate—simply a rule of thumb—for standard practice in the many diversified plants throughout the country where our products were expected to go. This has become confused with the 100 F metal-temperature "differential" which, with correct premises, is a measure of stress.

Starting-up rates, therefore, have no technical standing in themselves, but only as they are reflected in temperature differentials between parts of the structure.

Separate and distinct from the problem of clarifying a misunderstanding, and simply as a matter of general information, our field data indicate that a starting-up rate of 100 F per hr rise in saturation temperature will produce a temperature gradient through a normally insulated boiler drum of approximately $4\frac{1}{4}$ F per in. of drum thickness; and (extrapolating the data) that a starting-up rate of 460 F per hr will produce a temperature gradient of approximately 10 F per in. of drum thickness.

The latter part of the authors' supplement covers some data on the starting up and shutting down of high-pressure boilers. Two explanations are given with which it is necessary for the writer to disagree.

The first deals with the reason why the bottom of the 60-in. drum cooled faster than the top. The curves indicate that the bottom followed saturation temperature very closely and dropped only 12 F below saturation at the point of maximum deviation, while the temperature at the top of the drum registered 118 F above saturation at the same time. The effect of cold feed-water might account for the 12 F subsaturation temperature at the bottom, but it cannot account for the 118 F superheat at the top.

Superheating at the top of a steam and water drum during the shutting down of a modern boiler under normal water-level conditions is a common and natural occurrence.

In starting up or in raising steam pressure, the heat absorbed by the boiler and waterwalls generates steam which collects in the drum. That portion of the steam in direct contact with the

drum metal heats it through condensation. The temperature of the inner surface of the drum in the steam space is therefore, in effect, geared directly to saturation temperature. The lower portions of the drum in contact with the boiler water are heated very close to saturation temperature by the circulating boiler water.

In shutting down, the submerged parts of the drum are maintained close to saturation temperature by the boiler water because its temperature follows saturation on falling pressure the same as it does on rising pressure. The steam in close contact with the upper part of the drum, however, does not ordinarily condense on falling pressure, because as soon as the saturation temperature drops, the drum metal with its stored heat finds itself hotter than the steam in close contact with it and it therefore superheats this steam. The rate of heat dissipated from the upper part of the drum through radiation and through conduction is usually small as compared with the cooling rate of the boiler water in the tubes and, in turn, the cooling rate of the submerged portion of the drum. The temperature of the top of the drum consequently drops at a slower rate than that of the bottom. The superheat at the top therefore increases, even though both top and bottom temperatures are falling at their different individual rates.

Filling the drum to overflowing, as recommended by the boiler manufacturer, will, of course, re-establish the direct relationship in temperature between the top of the drum and saturation and thereby make it permissible to increase the cooling-down rate to the point where it approaches the limiting starting-up rate. This filling-up procedure does demand the making of provisions for overcoming a number of important operating objections.

The second point of disagreement deals with the cooling of nondrainable superheater tubes. There may be some very special cases in which the steam resulting from the evaporation of the condensate in nondrainable superheaters contributes materially to the cooling of the tubes, or to protecting them against overheating from relatively high gas temperatures, before they are cleared of condensate and before a through-flow of cooling steam from the boiler has been established. In the overwhelming majority of cases within our experience, however, it has been necessary to consider that those portions of the superheater tubes which are above the level of the accumulated condensate, and at the same time are in the path of the heating gases, should be considered as uncooled metal which is at the mercy of the gases. Until a throughflow of steam is established, by boiling out or by blowing out the condensate, we are convinced that the temperature of the gases entering those parts of the nondrainable superheater, which might be above the level of any trapped condensate, should be kept below the point at which uncooled tubes can be damaged. Many of the nondrainable units today are placed in service successfully without any special attention given to the gas temperature at the superheater entrance. This is made feasible by a number of fortunate relationships and by the 100-F rule-of-thumb starting-up rate. The power to do damage is present, nevertheless, and those who plan to increase their starting-up rates to 200, 300, and 400-F rise in saturation temperature per hour would do well to reckon with it.

A. R. WEISMANTLE.¹⁶ The principle of the quick start is simple and consists of admitting steam into a turbine at a temperature equal to or slightly higher than the metal temperature of the steam chest, and then increasing this metal temperature at a rate of not over 100 F per hr. The descriptions of the various trials made and the expedients resorted to by the authors, in order to accomplish these ends, clearly show us that they can-

¹⁶ Assistant Manager, Steam Division, Foster Wheeler Corporation, New York, N. Y. Mem. ASME.

not be attained without considerable complexity in operation of conventional steam-generating units.

On systems where quick starts are imperative, steam-generating units considerably more flexible than conventional units as to control of steam temperature should be used. This flexibility must include not only the usual control of temperature at constant level over a wide load range but also the ability to vary steam temperature from saturation up to the full design temperature over the same range. The positive control of steam temperature provided by such a unit at any temperature level throughout the load range makes it possible to fulfill the requirements of the quick-start procedure with ease and simplicity. With such units there is no need for special starting techniques which would differ between the various power teams in the system and require revision in accordance with the length of time a turbine was shut down.

Steam-generating units which provide this flexibility of steam-temperature control have been designed and built for many years. One unit of such design, known as the Foster Wheeler twin-furnace unit, is shown in Fig. 35, herewith. This unit consists of two furnaces and gas circuits which are arranged in parallel and completely separated up to the economizer inlet. From that point on the arrangement of components is conventional. One furnace is completely water-cooled, and the gases leaving this furnace pass over the boiler surface before reaching the economizer. The other furnace is partially water-cooled and partially steam-cooled, and the gases leaving this furnace pass over the superheater before reaching the economizer. By differential firing of the two furnaces it is possible to deliver to the turbine either saturated steam or steam with any amount of superheat up to the full temperature for which the unit was designed. Thus, for a quick start, this type of unit permits delivering steam initially to the turbine at a temperature equal to or slightly above the metal temperature of the steam chest and then it allows increasing the temperature at exactly the maximum rate permissible. The control of turbine metal temperatures is positive and is very simply obtained by differentially firing the steam generator. Those engineers associated with systems where quick starts are to be made with topping turbines, straight-condensing, or even reheat units should not overlook the important advantages offered by steam-generating units of this type.

The evolution of procedures for quick starts of the No. 9 unit at Sherman Creek, as described in the paper, is quite interesting. The authors explain that a by-pass is now being designed so that the superheater will be cleared of water and the desired steam temperature obtained before opening the throttle. This undoubtedly will prove a simple means for providing steam for admission to the turbine at a temperature equal to or slightly higher than the metal of the turbine steam chest. However, unless steam-chest temperature happens to be high, it would appear that excessive rates of temperature rise could still occur during the rolling and initial loading period. In order to avoid this, a simple spray-type desuperheater, located in the circuit between the superheater outlet header and the turbine throttle, could be installed and used for control during this period. Could the authors tell us whether they have yet been able to obtain any results with the by-pass on the No. 9 unit?

Referring to Fig. 25 of the authors' Supplement, it can be seen that even though they were able to match steam and chest-metal temperatures initially, thus eliminating the initial temperature shock, the rates of temperature rise during rolling and initial loading period are still high. It appears that the metal temperature increased at the rate of 420 F per hr and 750 F per hr on Waterside No. 6 and No. 7 units, respectively. Fig. 28 shows a quick start of No. 6 unit at Hudson Avenue, from a common header system, and it appears that the throttle-valve metal temperature increased at the rate of 930 F per hr during the roll-

FIG. 35 FOSTER WHEELER TWIN-FURNACE UNIT

ing period, with this setup. These items only serve to emphasize further that (a) steam-generating units considerably more flexible than conventional units as to control of steam temperature should be used for quick starts of unit systems, and (b) even though steam and metal temperatures are initially matched, excessive rates of temperature rise can occur during the rolling and initial loading periods when conventional boilers are used, unless some desuperheating control is added. This latter statement also applies to quick starts of machines from a common header system.

The authors have included a section on shutting down and starting up high-pressure boilers. While the data given on this subject are not too complete, it is most gratifying to observe that they are not reducing time arbitrarily, but only on the basis of results obtained by real investigation.

The time for starting up or shutting down steam generators is usually based upon three main considerations, namely, (a) preventing excessive stresses in drums and headers, (b) avoiding the overheating of superheater-tube metals, and (c) eliminating thermal shock at joints or stresses in parts.

Excessive stresses in drums and headers can occur because of circumferential or transverse temperature differentials encountered in the start-up or shutdown procedures. It is well known that approximate heat-transfer coefficients in Btu/hr/sq ft/deg are on the order of 2000 for condensing vapors, 600 for heating or cooling water, and only about 2 for heating or superheating steam. The thermal conductivity of steel is approximately 25 Btu/hr/ft/deg. From this it is quite apparent that the inner surface of the drum plate at or below the water level will always stay substantially close to the water temperature. Also, the inner surface of the drum plate above the water level will stay close to the saturation temperature when steam is present and pressure is being raised. However, the top half of the drum will be heated only by the slow process of conduction in the period before steam pressure is raised and will be cooled slowly by con-

duction and a very low transfer rate to steam during the period after firing has ceased. It is self-evident then that greatest metal-temperature differentials circumferentially may be expected in the period after light-off has occurred and before steam is formed, and also during the cooling-off period after firing has ceased. The greatest transverse metal-temperature differentials can occur during the pressure-raising periods or during an emergency shutdown when pressure is lost practically instantaneously.

If saturation temperature, corresponding to the pressure, is plotted in Figs. 32 and 33 of the Supplement, the analysis of the data becomes easy. The circumferential temperature differential of 130 F is readily apparent in Fig. 32. One might ask the authors, however, why the drum thermocouples read as much as 30 F above saturation temperature under load conditions, and why horizontal center-line couples on the 60-in. drum are as much as 50 F above saturation temperature during the shutdown periods, unless, of course, water level was held extremely low during this latter instance. Also, it can be seen that the metal temperatures at the bottom of both the 54-in. and 60-in. drums is practically at saturation during the shutdown period. In view of this fact, it seems questionable that the bottom of the 60-in. drum is cooling faster than the top because of the introduction of feedwater. Undoubtedly, it cools faster than the top because of the fundamental heat-transfer principles involved.

To provide maximum drum safety when units are started up or shut down quickly, it is imperative that drums be practically filled with water during the initial firing period until steam is formed and also during the final firing period just before firing ceases. Special gage glasses to facilitate this operation should be applied at the top of the drums. It has been our practice to supply many units with such special glasses for these purposes, but we have found that invariably operators avoid their use. They are essential, though, for quick starts and shutdowns.

Avoiding the overheating of superheater-tube metals is of utmost importance in the start-up of any steam generator. It is well known that the tubes of nondrainable-type superheaters become practically water-filled from condensation after shutdown. This water must be removed either by evaporation or displacement before the normal cooling flow of steam through the tubes can be established. As the water is evaporated, portions of the tube become steam-trapped, in effect, and at these locations metal temperatures can become considerably higher than the steam temperature. To clear all elements of water before going on the line and to keep metal temperatures at safe values, it is necessary that the gas temperature entering the superheater be at or below 1000 F and that all the superheater surface, especially the bottom loops, be gas-swept during the start-up procedure. By reason of thermocouple location, the temperatures obtained by the authors, and included in Figs. 32 and 33, are more truly outlet steam temperature than actual heating-surface-metal temperature. Because of this fact, the data do not necessarily indicate that metal temperatures were safe.

Note the rapid change in temperatures which occurred between the hours of 4:45 and 5:15, and again at 6:15 in Fig. 33. This rapid increase occurs when loops clear themselves of water and the temperatures then read are the steam temperatures leaving the elements after cooling flow has started. Under this condition indicated temperatures are in the neighborhood of 700 F to 800 F, so it is self-evident that metal temperatures must have been considerably higher when steam was not flowing through the elements. To avoid the possibility that metal temperatures are unsafe, thermocouples should be installed on the actual heating surface during the trial quick-start periods. To best protect the superheater, the unit should be started up with lower burners,

without any superheater gas by-pass and with as much steam flow through the elements as possible. If this is done and the criterion on gas temperatures is met, there is no alternative except taking the time necessary to stay within the limits mentioned, in order to assure superheater safety.

Eliminating thermal shock at joints or stresses in parts is always important in starting up or shutting down. Too often it is found possible to establish some average circulation and temperature rise throughout a section, while local tubes which may be covered with ash, or located at corners, or entering drums above the water level still remain cool. Considering that a temperature differential of only 140 F may produce a stress of 30,000 psi, and that when circulation establishes itself in these local sections, it occurs rapidly, the possibility of trouble from this factor becomes readily apparent. The authors' comments indicate that they have experienced this trouble even with normal slow starts. The writer does not think that quick starts will improve this condition.

Properly welded joints are less susceptible to leakage than rolled joints, but the important thing is to establish circulation early and uniformly. Frequent blowdown of all lower headers during the initial heating and pressure-raising period will assist considerably in this respect, or some other means of assisting circulation during this period can be applied. The data given by the authors on this phase do not permit detailed analysis. Fig. 33 shows water-wall-header temperatures which were measured as much as 100 F lower than saturation temperature during the pressure-raising period, and even when on the line at 500,000 lb of steam per hr. The authors should account for this, and tell whether it is couple error or whether such subcooling actually exists in this unit.

The start-up and shutdown time set for a given steam generator by the manufacturer is based upon consideration of all the factors mentioned in the foregoing. There is no doubt that this time can be reduced. We have put Navy boilers into full service from cold in 8 min without catastrophe. Many of us have experienced outages in which pressure was reduced instantaneously without trouble. However, we would all agree that these practices should not be followed blindly, especially in central-station work. Any procedures for reducing the time involved should be based on full consideration of factors which can cause trouble and use of expedients available for reducing the harmful effects, in order to assure safety and long operating life of the equipment involved. The authors are to be commended for their careful and intelligent approach to this problem.

AUTHORS' CLOSURE

As Mr. Casey observes, the temperature problems to be overcome in quick starting occur at the high-pressure end of the cylinder in the case of topping units, and at the exhaust end of the condensing units. This is due, in the first case, to unit systems having a tendency to have an initial steam temperature cooler than that of the steam-chest metal temperature, while in the case of condensing units this relation is favorable because they are generally supplied by a common header system. The exhaust end of the low-pressure units, however, presents temperature problems because of windage and initial poor vacuum.

In compliance with Mr. Casey's request, we are submitting the details of the \$250,000 saving given in our paper. The computations were based on 300 days of operation in which 30 condensing units and 2 topping units were started daily. The steam normally required for starting each of these machines is 50,000 lb and 300,000 lb, respectively, for condensing units and topping units, and by quick starting, the steam saving amounts to 70 per cent. The coal rate was taken at 9 lb of steam per pound of coal. The cost of the coal was figured at \$9 per ton. The aux-

iliary power saved daily because of the shortening of the rolling time of the above 32 units was calculated to be \$100 per day. On this basis the saving was

$$300 \left[100 + 9 \times \frac{0.7}{9 \times 2000} (30 \times 50,000 + 2 \times 300,000) \right] \\ = \$250,500 \text{ per year}$$

This figure shows only the saving expected in fuel. Furthermore, at East River Station quick starting has permitted a reduction of the midnight shift to a skeleton force. This has resulted in an annual labor saving of \$130,000. When quick-start procedure is applied to all machines, further saving in personnel is expected.

Mr. Cross's comments were of particular interest to us, and his thorough endorsement of our work was most gratifying. We agreed with Mr. Cross that some variations in the operation of shutting down and quick starting of boilers may be necessary to take care of the differences in design.

As usual, we found ourselves in full agreement with Mr. Dahlstrand, and we take this opportunity for reiterating our appreciation for his contribution on quick starting of turbine generators.

By comparing thermocouple readings 8 and 9 on Fig. 30 which gives the temperature difference across the horizontal flange of No. 9 unit at Waterside, Mr. La Motte can see that this differential exceeded the 200 F set as a limit by the manufacturer and that a crushing of the inner edge of the horizontal joint could have resulted. However, this 200 F differential did not occur during the start but only after the unit had been phased in for about one hour and kept on increasing until it reached a maximum of 350 F an hour and a half after being put on the line. As the unit had been started many times previous to this test, and without the benefit of thermocouples 8 and 9 to guide us, it can be assumed that the crushing of the joint inner edge took place soon after the unit was commissioned. The possible remedy indicated by Mr. La Motte would be a valuable corrective step on existing installations. However, we believe that on new machines, double-shell construction is the practical solution so as to divide the temperature gradient between two horizontal flanges.

We have found Mr. Reynolds' discussion of our paper very informative. The possibilities of rub being caused by cylinder "humping" is, of course, one factor which continues to give us great concern, not only for the quick start but even more so for normal starts. We would like to suggest to the manufacturers for their study, the design of a new supervisory instrument which would give the operator the knowledge of, and the means of measuring this cylinder bowing. If such a tool could be devised we feel it would contribute as much toward safer operation as did the measurement of shaft deflection prior to the rolling of a unit.

Quick starting was, in fact, imposed upon us by the load characteristic of the City of New York. Our contribution was merely to demonstrate its safe possibility and evolve the procedure. Quick starting was intended to relieve the early morning rush created by the necessity of simultaneous starting of many units which had had to be shut down late the night before. Today, this objective is still the same. For longer shutdown periods,

generally over 8 hours, we do not retain the 15-minute starting cycle but adopt longer rolling periods depending, as Mr. Reynolds pointed out, upon the length of the shutdown period.

The clarification given by Mr. Savoye as to how the 100 F rule came into being and its general misinterpretation, is revealing and we suggest that every boiler operator who has the opportunity to read Mr. Savoye's clear explanation make every effort to understand and remember the valuable information given in his comments.

On the matter of divergence in the rates of cooling between top and bottom of the drum during shutdown, Mr. Savoye disagreed with our interpretation of the cause but arrived at the same conclusion, namely, that the corrective measure consists of filling the drum.

We fear that we have been misunderstood by Mr. Savoye in regard to the cooling of nondrainable superheater tubes. It has not been our intention to demonstrate that steam resulting from evaporation from the accumulated condensate in these nondrainable tubes contributed to their cooling during starting. On the contrary, we have been proposing to generate, in the quickest possible time, by accelerated firing, a large volume of steam which would establish a mass steam flow of sufficient intensity to clear the superheater tubes of the condensate. It is our belief that the proposed by-pass around topping units will accomplish this purpose successfully.

Mr. Weismantle inquires about the status of the by-pass around No. 9 unit at Sherman Creek station. As of this date, the by-pass is not in operation but all connections which could be made without a long outage of the unit are in place, and we hope that in another two or three months the by-pass will be in service.

We have no explanation to offer regarding the 30 F above saturation which was present in the 54 and 60 in. metal drum temperature when the unit was under load but about ready to be shut down, except, perhaps, that it was due to a transient condition during this unsettled period. The close agreement of the saturation temperature with that of the drum metal during the subsequent start, would indicate that the condition of the thermocouples was excellent and that this above-saturation-temperature, although not explainable, did really occur.

During the overnight shutdown test, as shown in Fig. 32, the water was held at the normal level which, in this Combustion boiler, is below the center line of the drum. Therefore the reason for the 50 F differential between thermocouples located in the middle of the drums and those at the bottom appears to be due to the slower cooling of the drum metal above the water level. Here again we are pleased to see that, regardless of the reasons for this differential, Mr. Weismantle also advocates the same curative procedure of filling the boiler drums to overflowing as soon as the boiler is taken off the line, and keeping them full until the pressure is reduced to the desired point.

At this time it is not possible to vouch for the accuracy of the thermocouple readings of the waterwall header temperatures. While we suspect that 100 F differential is greater than it should be, we are, nevertheless, satisfied that a temperature lag exists between the waterwall header temperature and the saturated temperature, with the former being lower during starting operations.

Sealing of High-Pressure Steam Safety Valves

By R. E. ADAMS¹ AND J. L. CORCORAN²

A fundamental investigation of sealing with high-pressure steam safety valves has shown that poor sealing is a result of self-induced growth of tiny initial leaks. Expansion of the leaking steam cools local areas of the valve seat, causing contraction of the seating surfaces in a manner which increases the size of the leak. A new design of valve seat was developed, incorporating thin flexible seating surfaces. The cooling effects of the leaking steam were minimized by providing better heat transfer from the high-temperature steam. The new design resulted in considerable improvement in sealing, and service tests have shown excellent performance.

INTRODUCTION

THE two primary requirements of steam safety valves are (1) that the valves open without fail and release steam efficiently when the popping pressure is reached, and (2) that the valves close at a slightly lower pressure and prevent leakage of steam at all pressures under the closing pressure. The methods of popping and closing the safety valves are well understood. However, the problem of leakage of steam safety valves has long been recognized by designers as one of the most difficult problems which they face.

The essential elements of a safety valve, in so far as sealing is concerned, are the feather and the seat bushing. The seat bushing is simply a hollow tube connected to the boiler, with a carefully finished seat on the top surface, while the feather is essentially a cover with a similar seat held against the seat bushing by pressure from a spring. When the steam pressure on the bottom of the feather exceeds the force of the spring, the design of the valve is such that the feather pops up and steam is released until the pressure drops to a predetermined value. At that point the feather is forced down by the spring, and the valve is again closed.

The reason for the difficulty of sealing with safety valves, as compared with other types of valves such as shutoff, gate, and globe valves, or the like, is that with these latter types of valves, a tremendous load can be imposed on the mating parts of the valves by simply increasing the closing force on the operating handle of the valve. In direct comparison to this, on safety valves the seating surfaces are held together only by the difference in loading between the set load of the spring and the operating pressure of the steam.

This differential load is quite small, because it is naturally desirable to operate a boiler at a pressure as close to the maximum allowable working pressure as possible. Since the maximum allowable working pressure is the setting of the safety valve, the gap between the set and operating pressure of the safety

valve is of vital interest to the designer. The economics involved in making this gap as small as possible constitutes a compelling factor of boiler design. Thus there can be no wide difference between set and operating pressure.

Many factors contribute to leakage in valves. Among the most important is distortion of the seating surfaces caused by outside influences including installation strains, piping, hook-up, and ambient temperatures, particularly on outdoor installations. Further than this, any minute amounts of dirt or foreign material lodging on the seats, together with damage caused by grit in the steam, can also be causes of safety-valve leakage.

Another serious problem in connection with safety-valve leakage is that when leakage starts, for any reason, continued operation of the pressure vessel at the normal pressure will result in continual leakage of the valve. This leads to erosion of the seating surfaces and to increases in leakage to the point where the boiler must be taken out of service in order to recondition the valve.

As the steam pressures have increased in the past 25 years the problem of safety-valve leakage has become increasingly severe. This was particularly true as pressures rose above the 600 to 900-lb class to 1500 lb and above. It was the general experience of safety-valve users that valve designs which could easily be maintained tight at 600 and 900-lb pressure proved to be a considerable problem at 1500 psi.

This problem had existed for many years with only varying degrees of success in improving sealing in various plants throughout the country. Many different techniques of seat finishing, changes in design, and the like, were tried out, with some slight improvement in the standard of tightness of the valves at 1500 psi, but without making any decided change in the over-all picture.

Because of this, it was decided that a fundamental research investigation of the cause of safety-valve leakage was essential. This would not be a study of the past efforts made toward solving the problem. Instead, it would be an approach from a fundamental basis by someone entirely separated from the problem, who would not be subject to past knowledge which might be a hampering restriction.

LABORATORY INVESTIGATION OF SEALING

Apparatus Used. Accordingly, an experimental laboratory investigation to study the sealing of safety valves was started. A standard 3-in. safety valve designed for operation at a pressure of 1500 psi was used as the test valve.

Two types of materials for the feather and the seat bushing were of interest in this investigation. One was a ferritic turbine grade of stainless steel, known as Type "T," containing about 14 per cent chromium and 0.12 per cent carbon. The other type, known as Stellite trim, had seating surfaces of Stellite welded onto an austenitic stainless-steel base.

Fig. 1 shows a schematic drawing of the steam generator designed and used for laboratory sealing tests with the valve. The boiler consisted simply of a steel pipe, capped at the lower end, with a standard 3-in. flange at the top for connection of the test valve. The boiler had a capacity of about 100 lb of water

FIG. 1 DIAGRAM OF LABORATORY TEST BOILER

which was added before attaching the valve. Heat was supplied by eight separate electric resistance elements wound around the outside of the pipe, the connections so arranged that the heating elements could be connected in several different combinations to provide the desired degree of heating. Thermocouples were placed at various positions on the boiler to insure that no sections became overheated. This steam generator proved to be entirely satisfactory for the work, and pressure could be controlled easily by proper manipulation of the connections of the heating elements.

Test Technique. The valve could be made to pop with this boiler, but early tests indicated that popping was not essential to the investigation of sealing. The technique finally used for sealing tests was about as follows. The boiler pressure was raised slowly, the power being shut off as soon as rapid leakage started, so that the valve did not usually pop. With this method of testing, the valves leaked more rapidly and to lower pressures than they normally would in service. This is partly because, when a valve closes after popping, it closes with considerable impact, which assists in obtaining tightness.

The pressure at the time rapid leakage started was considered as the popping pressure; for most tests it ranged between about 1100 and 1250 psi. To facilitate comparison among various tests, pressure data are reported as per cent below the popping point.

Leakage was measured by condensing the leaking steam, an aspirator being used to pull the steam through the condenser. Leakage rates are reported as cubic feet of steam at atmospheric pressure per hour. Leakage rates ranging from about 6 to 600 cu ft per hr could be measured.

As part of the fundamental investigation, some early tests on the valves were made using tank nitrogen as a source of high-pressure gas. Leakage with nitrogen was determined by measuring the rate of displacement of known volumes of water from a burette connected to the steam outlet of the valve.

Preliminary Tests. The results of sealing tests with nitrogen indicated that misalignment of the various parts of the valve within plant tolerances had little effect on sealing. It was found that considerable improvement in sealing with nitrogen could be realized by using a higher-polished finish on the seating surfaces.

Tests with steam, however, indicated that sealing was not improved by the better finish on the seating surfaces.

Characteristics of Sealing With Nitrogen and Steam. The steam tests did reveal that sealing with steam was radically different from sealing with nitrogen. At 10 per cent below the popping point, steam leakage was found to be about 600 times greater than with nitrogen; and at the normal closing pressure of 4 per cent below the popping point, steam leakage was estimated to be several thousand times greater than the leakage obtained when testing with nitrogen. It was then realized that sealing as obtained with nitrogen was undoubtedly adequate for service requirements, and efforts were then directed toward defining the differences which existed between testing with steam and testing with nitrogen. A major difference between sealing with steam and sealing with nitrogen was noticed in leakage tests with successively increasing and decreasing pressures. This is shown graphically in Fig. 2. The upper curve, for nitrogen, shows that the rate of leakage gradually increased as the pressure increased. Only very moderate leakage occurred until the popping pressure was reached. On reducing the pressure, after leaking rapidly at the popping point, the leakage rate was only slightly greater than when the pressure was increasing.

FIG. 2 LEAKAGE-PRESSURE RELATIONS WITH STEAM AND NITROGEN

With steam, a very different situation existed. As the pressure was increased from a low value, leakage at first gradually increased, as with nitrogen, along the line AB. At some pressure slightly below the popping point, such as B, the leakage suddenly increased to an enormously high value along the line BC. If pressure were still further increased, leakage increased slowly until it was sufficient to cause the valve to pop. However, if at point C the pressure were decreased, the line CB could not be retraced; instead, the leakage remained quite high to a much lower pressure, as shown by the line CE. At point E, leakage

died down suddenly to a normal value F , and if pressure were increased at that point, leakage would then retrace the line FB . The difference in behavior of the two gases was striking, and it was evident that if the reasons could be discovered, a solution to the problem of poor sealing could probably be devised.

It was first thought that the effect of the leaking steam might be to introduce thermal gradients in the valve body, causing it to distort and force the feather away from its true position. Temperature measurements of the valve body did show that temperature gradients existed. However, when these were eliminated by heating the entire valve to the steam temperature, the improvement in sealing was negligible.

Temperatures of Valve Trim. In a further effort to determine the cause of rapid leakage with steam after leaking had once started, temperatures of the valve trim were studied during a leak test. In a test with Stellite valve trim, thermocouples were welded to the side of the feather, the location of the beads being indicated in the diagram of Fig. 3(a). Although the thermocouples were not protected from the steam, good thermal contact between the thermocouple beads and the feather was assured since the beads were spot-welded to the feather. Fig. 4 shows graphically the temperatures that were recorded during a sealing test.

FIG. 3a (left) LOCATION OF THERMOCOUPLE BEADS ON STELLITE FEATHER

FIG. 3b (right) LOCATION OF THERMOCOUPLE HOLES IN TYPE T BUSHING

A similar test was made using the Type T valve trim. For this test, the thermocouples were spot-welded to the bottom of small holes drilled in the seat bushing, so that the thermocouples could be completely shielded from the leaking steam. Locations of the thermocouples are shown in Fig. 3(b). The temperatures at various points around the seat bushing are shown graphically in Fig. 5.

In both of these tests, the valve-trim temperatures were quite uniform up until the time leakage started. At that point, temperatures at several locations dropped considerably. When the valve was leaking badly, severe temperature gradients were observed in the valve trim, the temperature at one point of the feather being more than 200 F below the temperature at another point. As the boiler pressure dropped and leakage became less, the thermal gradients in the valve trim also decreased. When pressures dropped to the point that all leakage had ceased, the valve-trim temperatures had returned to about their original values, and the thermal gradients no longer existed.

It was thus apparent that the leaking steam was cooling the seat surfaces. The temperature differences measured in the

FIG. 4 TEMPERATURES OF STELLITE FEATHER DURING LEAK TEST

FIG. 5 TEMPERATURES OF TYPE T BUSHING DURING LEAK TEST

seat bushing were less than those noted on the feather for a number of reasons. Leakage was considerably less with the Type T trim than it was with the Stellite trim. The thermocouple beads on the Stellite feather were located practically in line with the steam flow, and would be cooled directly by contact

with the steam. In the seat bushing, the beads were well shielded from the steam, and were located essentially between the cooled area of the seat and the hot body of the bushing, the body of the bushing being maintained at a higher temperature by contact with the hot steam over the entire internal diameter. Thus it seems likely that the thermocouples on the feather measured approximately the temperature of the leaking steam, while the thermocouples in the seat bushing actually measured the temperatures of the seat bushing at a finite distance below the seat surface.

Cooling of Throttled Steam. The thermal gradients found in the valve trim were caused by the cooling of the steam as it expanded through the valve seat. When any gas is allowed to expand through a small orifice it expands in approximately a throttling process, and an imperfect gas will be cooled. The amount of cooling for steam depends upon the initial pressure and the degree of superheat. Fig. 6 shows the degree of cooling induced as steam of various qualities is allowed to expand from different pressures by the throttling to atmospheric pressure. Saturated steam at 1000 psi cools about 250 F when expanded to atmospheric pressure by a throttling process. Nitrogen, a far more perfect gas, cools only about 6 F during throttling from 1500 psi.

Fig. 6 COOLING OF STEAM AND NITROGEN WHEN THROTTLED TO ATMOSPHERIC PRESSURE

Mechanism of Leakage. From this information a theory of leakage of steam safety valves was developed. If a tiny steam leak exists at some point on the valve seat, the local area near that point is cooled, and the metal tends to contract. This contraction causes deformation of the valve seat in two ways, first, by direct contraction perpendicular to the seating surfaces, and second, by contraction in a direction parallel to the circumference of the seat. Both act to increase the size of the gap between the feather and the seat bushing at the local area of leaking.

Thus, once steam starts to leak through the valve seat, the size of the gap increases rapidly until the rate of leakage is extremely high. When pressure on the valve is reduced, rapid leakage does not stop until the differential force on the feather is sufficient to overcome the warpage caused by the thermal gradients. Thus the reason for the great difference in sealing with increasing pressure and decreasing pressure with steam, and the difference in sealing between steam and nitrogen is explained.

Agreement Between Theory and Experience. Many of the fac-

tors which plant experience had shown to be characteristic of sealing could be explained on the basis of this theory of leakage. Sealing was more difficult to obtain with higher pressures because the cooling effect from the expansion of throttled steam increases directly with pressure, as shown in Fig. 6. Similarly, sealing was worse for saturated steam than for superheated steam because saturated steam cools more when it expands in a throttling process. The difference in sealing between the turbine-type stainless steel and the Stellite trim could be explained by their differences in thermal expansion, the coefficient of thermal expansion for the Stellite and for the austenitic base both being about 45 per cent greater than for the Type T material.

Possible Methods for Improving Sealing. On the basis of this theory of leakage, several possible means of improving sealing could be considered. These are as follows:

- 1 Keep initial leaking low; if the amount of initial leaking could be kept nil after the valve popped, the self-increasing cycle of leakage could not start.
- 2 Use a seating material with a low coefficient of expansion, since such a material would produce less deformation with a certain degree of cooling. Consideration of various materials divulged that a high-temperature cobalt invar had an expansion coefficient of about 4×10^{-6} per deg C, about 60 per cent less than that of the turbine-type stainless. It appeared that only a limited improvement in sealing might be expected from such an attack.
- 3 Use valve-seat materials with high thermal conductivity, so that the thermal gradients induced in the valve seats would more readily equalize. However, most materials which have high thermal conductivity are not suited for use with high-pressure steam; also, only a limited degree of improvement could be expected from this attack.
- 4 Reduce thermal gradients in the valve seat by providing a short heat path between the seating surfaces and the hot steam.
- 5 Decrease the rigidity of the valve seats, so that less pressure differential would be required to overcome any distortion of the valve seat.

New Design of Valve Seat. It was soon apparent that a change in design of the valve seat offered the best means of minimizing the characteristics responsible for poor sealing. Accordingly, a new type of valve seat was designed, in which the seating surfaces were undercut to provide relatively thin seating surfaces. Fig. 7 shows a drawing of the modified valve seat. Three advantages were expected of this design; these are listed as follows:

- 1 Thermal gradients in the valve seat would be reduced. The cooling effect of the steam as it leaked would be counteracted by the hot steam on the back of the thin elements. This would provide a high rate of heat transfer, and any cool sections on the seating surfaces would be effectively heated.
- 2 The thin elements could deflect easily under very slight differential pressures, and readily accommodate any warpage or distortion of the seating surfaces.
- 3 The entire force of the steam pressure would act to hold the thin edges of the seat closed. Because of this, it was expected that sealing would be largely independent of the spring load on the valve seat.

A detailed drawing showing dimensions of the first experimental valve seat of this design is shown in Fig. 8. The seat was designed so that when the full load of the spring was on the feather, or during the impact of closing after a pop, the thin edges would deform elastically, so that the load would be carried by the thicker portions of the valve trim. However, when steam pressure was such that the spring load exceeded the gas pressure by only about a hundred pounds, the entire load would be

FIG. 7 ASSEMBLY DRAWING OF NEW-DESIGN VALVE SEAT

carried by the thin portions, so that the seat would be quite flexible in the range of pressure where poor sealing occurs.

Although this design has been considered from the aspect of a conical-seated valve, it should be equally applicable to designs of flat-seated valves.

Laboratory Sealing Tests With New Design of Valve Seat. Sealing tests were made with the new design of valve seat, as well as with a conventional valve seat of the Type T material. Prior to the steam tests, both types of valve trim were tested with nitrogen to insure that no serious defects existed in the seating surfaces.

The results of the sealing tests with steam are shown graphically in Fig. 9. With both types of trim, steam leakage was small at first and fluctuated considerably. The maximum values of leakage with the conventional seat were reached after the pressure had dropped to between 1 per cent and 5 per cent below the popping point. This simply indicated the finite time required for the thermal gradients and deformation of the valve trim to develop after the initial leaking started.

Characteristics of the sealing tests are discussed in the following paragraphs.

Type T Trim. With nitrogen, this set of valve trim was found to seal about as well as those which had been tested previously. The leakage curve for the Type T trim is the basis for judging the sealing characteristics of the modified design.

New Seat Design. The great improvement in sealing with the new-type valve seat is clearly indicated by the data. When tested with nitrogen, sealing with this trim was about comparable to that of the conventional seat. When tested with steam, leakage with the new design at 4 per cent below the popping point was as low as with the conventional valve seat at 12 per cent below the popping point. It had been expected that initial leakage would be lower for the new design than for the conventional trim, owing to the flexibility of the seating surfaces. However, the tests with nitrogen indicate that initial leakage with the new design was probably quite comparable to that ob-

FIG. 8 ENLARGED VIEW OF NEW-DESIGN VALVE SEAT

FIG. 9 SEALING TEST DATA WITH TWO VALVE-SEAT DESIGNS

tained with the Type T trim. Thus it seemed that the excellent sealing with steam must have been due in a large part to the better heat conduction to the seating surfaces.

Plant Tests With the New Design. Since such excellent results had been obtained in sealing tests with the new design of valve seat in the laboratory, it was sent to the plant for further investigation and development.

The first step in this was an exhaustive test of the valve which had been tried out in the laboratory. The valve was tested at 1200 psi steam pressure over a period of some three weeks, the valve being tested periodically by popping and then being left under loading for a period of time.

At the end of the testing, the valve having been subjected to a total of some 200 pops, the seats were examined. There were no signs of seat deformation or failure, although some wear had occurred on the seating surfaces.

This indicated that the idea embodied in the undercut seat was of a sufficiently rugged nature that it would withstand continuous service blowing, and that the research results should be developed into a practical design.

Development of the Thermosdisc Design. An analysis of expected field conditions naturally showed that it would be desirable to incorporate the design changes only in the feather, inasmuch as this part would offer the best opportunity for replacement when wear occurred. Undercutting of the bushing could be done, but slight wear might necessitate replacement of the bushing, which is a more difficult task.

Accordingly, the development was aimed at developing a design which would give the required heat conductivity and flexibility without embodying any fundamental objection in the way of field maintenance.

Further analysis of past experience showed that if the seat were made so thin as to be very flexible at the lower edge, as had been first proposed, there was more danger of potential damage to this seat from grit passing through the safety valve. This is based on experience, particularly with superheater valves, from the fact that very hard particles in the steam actually pit and abrade the noses of the safety-valve feather disks. It could easily be seen that a durable edge on the undercut seat would be desirable.

In addition to this factor, making the seat edges quite thin would result in very close tolerances in manufacture and would increase the cost of the design.

With all of these considerations in mind, a large number of variations in angles, thicknesses, and depth, were tried out, finally arriving at a thickness of 0.012 to 0.015 in. at the bottom edge of the seat, with a slightly deeper recess than had been indicated in the original design.

Plant Tests of Thermosdisc Design. Having determined the design which seemed to be most practical from the field-service viewpoint and from the manufacturing viewpoint, a series of

breakdown tests to determine the feasibility of the design were carried out.

One of these tests consisted of the continuous popping at 1200 lb of one of the seat elements over a period of time. The valve was blown rapidly and continuously for a total of 200 times and then was subjected to chatter or very rapid popping to determine whether seat damage would occur from this type of operation.

At the end of the test, the valve seat showed no damage in so far as breakdown of the seating element was concerned, although the seating surfaces showed wear, and a slight amount of leakage had developed.

A test for measuring the fatigue life of the seat element was worked out using a cam-operated weight-loaded device which dropped the seat for the distance of its normal lift with a weight of 200 lb, so the disk would strike the bushing with considerable force.

With this mechanism, the seat was subjected to a test of 80,000 cycles to determine whether or not fatigue of the seat element would develop.

At the end of the test, the disk and seat were still structurally perfect and showed no signs of fatigue failure.

Service Results With Thermosdisc Design. The first experimental Thermosdisc seats were put into service in late 1944 and initially resulted in a tightness comparable with that which had been realized experimentally during the research development phases. It was found necessary to incorporate a deflecting piece on the nose of the Thermosdisc comparable in contour to the older solid-disk design in order to eliminate a high-pitched noise which originated, apparently due to the recess in the seat.

Of the Thermosdiscs which were put into service initially in late 1944, two were later removed for examination and several are still in service at the original plant.

Following the initially successful testing of the Thermosdisc design and the checking of these after about six months' service, early in 1946 a complete change-over of a large high-pressure utility was made, all of the Thermosdiscs giving very good results as to tightness and operating characteristics during this installation.

Since that time, several hundred of the Thermosdiscs have been put into service with equally good results, at pressures ranging up to 2650 psi.

ACKNOWLEDGMENT

This research was done in co-operation with Manning, Maxwell & Moore, Inc. Their permission to publish these results is greatly appreciated.

The work at Battelle was under the direct supervision of Dr. H. W. Russell and Dr. R. W. Dayton. Their assistance throughout the work was very helpful. The idea for modification of the valve-seat design was conceived by Dr. Dayton.

New Method for Bulk-Modulus Determinations

By S. LOGAN KERR,¹ L. H. KESSLER,² AND M. B. GAMET³

The bulk modulus of fluids other than water has not been reported in engineering literature to any extent, particularly in the range of pressures and temperatures ordinarily encountered in petroleum pipe-line work. In pipe-line work it is desirable to make surge investigations in advance of construction, and this requires some knowledge of the pressure wave velocity in the system for computing the magnitude of surges which may be expected in ordinary operating or in emergency conditions. While the physical characteristics of the materials and construction of the pipe line itself are known, the same is not true of the physical characteristics of the liquid. This paper relates to a method of determining the bulk-modulus values of fluids other than water to make available the missing factor in pipe-line design considerations.

INTRODUCTION

IN any computations concerned with so-called "water-hammer" or surge conditions occurring when the flow rate of a liquid is changed in a closed conduit, the compressibility of the liquid and the elasticity of the conduit walls have a major effect upon the magnitude of the surge, as well as its distribution along the conduit.

The magnitude of the surge is directly proportional to the velocity of the surge wave and this, in turn, is affected by the diameter, thickness, materials of construction, and modulus of elasticity of the pipe walls. The character of the liquid in the pipe line also enters into the conventional equation for surge-wave velocity, with both specific gravity and compressibility affecting the values. The conventional formula for surge-wave velocity is as follows

$$a = 12 \sqrt{\frac{w}{g} \left(\frac{1}{k} + \frac{d}{Ee} \right)} \quad [1]$$

where

- a = velocity of pressure wave, fps
- w = weight of 1 cu ft of liquid, lb
- g = acceleration due to gravity, ft per sec²
- d = diameter of pipe, in.
- e = thickness of pipe walls, in.
- k = bulk modulus of compressibility of liquid, psi
- E = modulus of elasticity of material of pipe walls, psi

The specific gravity under various temperatures and pressures can be determined without great difficulty. The compressibility

factor, more commonly expressed as the bulk modulus of compressibility, is not so easily arrived at.

The bulk modulus can be calculated as follows

$$k = \frac{\Delta p}{\Delta V} V \quad [2]$$

where

- k = bulk modulus of liquid, psi
- Δp = pressure increment, psi
- ΔV = volume decrement produced by pressure increment Δp
- V = original volume in same units as ΔV

The bulk-modulus value for water at ordinary temperatures and pressures has been reported in a number of publications and is commonly taken as 300,000 psi for most surge calculations.

The bulk modulus of fluids other than water has not been reported in engineering literature to any great extent, particularly in the range of pressures and temperatures ordinarily encountered in petroleum pipe-line work (0 to 1500 psi, and 32 F to 100 F).

To make surge investigations in advance of construction of a pipe line requires some knowledge of the velocity of the pressure wave within the system for computing the magnitude of surges which might be expected due to ordinary routine operation or due to emergency conditions.

The physical characteristics of the materials and construction of the pipe line itself are fairly well known. The remaining factor relates to the physical characteristics of the liquid, and it is to these matters that attention is directed in this paper.

REVIEW OF LITERATURE

Some of the earliest work done on the determination of surge-wave velocity in liquids other than water was in connection with the studies of fuel-injection systems for Diesel engines.

Unfortunately, the investigations were carried out at fairly high injection pressures in the range from 1000 to 6000 psi, or even greater, and very little information is available for pressures below 1000 psi. The variation of compressibility or variation of bulk modulus with temperature has also been investigated to some extent, but here, too, the experiments were conducted at pressures on the order of several thousand psi and did not cover in detail the range in which petroleum pipe-line designers are primarily interested. There is included at the end of this paper a brief Bibliography listing some of the important references.

In almost every case, the determinations have been made by measuring, as accurately as possible, the quantity of additional volume of fluid required to compress the initial volume of material to various pressures. The means of measuring the increment of volume are varied, and some of the apparatus used a precision measurement of the displacement of a piston and in other cases a mercury pump was employed.

Hyde (1)⁴ measured the position of a sleeve on a plunger (8 mm bore and 12 cm long) before and after the application of pressure and determined the decrease in volume of the liquid in the small cylinder having a volume of 15.56 ml. Tyrer (2) worked at not more than 2 atm pressure with soft soda-glass and copper com-

compressibility piezometers of 500 ml capacity. He attempted to change the pressure and measure the volume change before any of the heat produced in compression had been lost.

Le Mesurier and Stansfield (3) used the device shown in Fig. 1; *A* is a steel cylinder with vent plug *B* and gland *C* fitted with a slow-speed engine fuel-pump piston *D* surrounded by split washer *E* at the outer end. *E* is held tightly in place with a spiral spring *F* surrounding the groove in the halves of the washer. The inner cylinder was filled with test fluid and lowered into the outer cylinder *G*, which was filled with fluid at the same temperature as the sample. The outer cylinder was sealed by cap *H*. Pressure was applied directly to oil in *G* and to plunger *D* and hence to sample in *A*, the washer being in contact with the outer end of gland *C* moved a distance proportional to the decrease in volume of the test sample. When direct pressure was released, the plunger was forced out of the gland by the expanding sample and carried with it the washer. Measurement of movement of the washer allowed the volume change of the oil when under pressure to be calculated from known dimensions of the plunger. No dimensions of the device are given. Le Mesurier assumed no strain in the material of the test vessel, because of balanced pressures, but Davies (3) states that there is a stress present, although Le Mesurier believed it to be so small as to be negligible.

Talbott (4), Fig. 2, used a copper tube screwed to the cover of a thin sealed vessel *A*, fitted with an insulated filling cup *B* at its upper end, and a copper pot *C* at its lower end. A fine platinum wire was attached to the filling cup and passed a short distance down the center of the tube. The inner vessel was surrounded by a cylinder of adequate strength, the liquid to be tested was placed in the inner vessel, and mercury was poured into the tube and copper pot to form a mercurial seal. The space between the inner and outer vessels was filled with distilled water, and hydraulic pressure was applied. This pressure was transferred through the mercury to the test liquid so that the inner vessel contracted in volume as a solid under hydrostatic pressure until the circuit was completed when the mercury contacted the platinum wire. The entire apparatus was surrounded by a water bath.

Cap *D* was removed and mercury added or removed until the electric contact was broken at atmospheric pressure. A weighed quantity and, therefore, a known volume of mercury was added to the filling cup, and the pressure necessary to break the contact was found. The pressure was measured by an optical gage, and a lamp indicated when contact was broken. A telescope and scale were used for the pressure gage, and the lamp was placed in the field of view of the telescope.

Talbott's experimental results were corrected for decrease in volume of the containing pot, the compressibility of the mercury, and for rise in temperature due to compression, because he applied maximum pressure in 10 sec.

These experimenters used devices employing a thin-wall test chamber and balanced the internal and external pressures, but apparently did not use dead-weight testers for pressure application or to determine unit pressure applied. In all of these instances, however, the volume and pressure increments were read when the apparatus was under pressure. Some question has been raised as to the accuracy of these measurements, particularly in relation to leakage from the apparatus, leakage past a piston or stuffing box, or the displacement of the liquid within the pressure-measuring device.

JOINT SURGE CONFERENCE

During investigations authorized by a Joint Surge Conference, set up to study the surge conditions within petroleum pipe lines, particularly those carrying crude oil, the need for accurate data on the compressibility factor was immediately apparent.

Some determinations had been made experimentally, but it was finally agreed that an independent investigation would be desirable to check the bulk modulus for the particular oils being transported under conditions existing during the field-test work.

A conference was arranged between the three authors of this paper to conduct a program of tests⁵ in which the effect of variations of temperature and pressure on bulk modulus within ordinary ranges could be determined, using a small sample of the actual fluids flowing through test pipe lines. It was felt that certain basic-design conditions for the apparatus should be fixed to avoid the potential errors believed to be present in the methods used in other investigations.

These fundamentals of design were as follows:

- 1 The apparatus should eliminate leakage or slip in relation to the measurement of the volume increment.
- 2 The apparatus should eliminate, in so far as possible, any effect of volume change due to the pressure-measuring device.
- 3 The apparatus should incorporate a dead-weight-gage tester for basic pressure measurement and avoid the use of a Bourdon-tube-type pressure gage, except for approximate indications.
- 4 The volume change of the apparatus itself under varying pressures and temperatures was also to be kept at a minimum.
- 5 The measurement of the increment of volume (ΔV) was to be made at atmospheric pressure and under conditions whereby this increment could be read to an accuracy of 1 per cent or less.
- 6 The over-all accuracy of the bulk-modulus determination at any given temperature or pressure should be within plus or

⁵ These tests, made in 1949, were part of a program instigated by the Joint Surge Conference of individuals representing Middle East Pipelines Limited, Trans-Arabian Pipe Line Company, and Gulf-Shell Pipe Line. The test results are included in the "Final Report of Joint Surge Conference" (13), which has been made available to the national engineering societies and to interested individuals and companies.

minus 2 per cent on an individual run and within plus or minus 1 per cent on a series of runs, using an average curve through the individual test points.

It was immediately apparent that with this basis for design, none of the apparatus described in the various technical publications could be used. Therefore a new design was developed to perform these experiments in a completely different way from that described in the literature listed in the Bibliography.

Instead of measuring the quantity of liquid required to raise the pressure a given amount, by observing the displacement of a column of mercury or a piston, the new apparatus was arranged to build up the pressure to the desired value, as measured by a dead-weight-gage tester. The pressure was then constant throughout the system, and by closing a valve it was possible to trap the total volume (initial V plus ΔV) within the pressure chamber.

The pressure was relieved by gradually opening a valve connected to a precision-graduated microburette until atmospheric pressure was reached. The difference between the initial reading and the final reading on the calibrated glass tube represented the increment of volume released and thus gave the value of ΔV . The initial total volume V of the chamber was determined by dimensional measurement and also by a volumetric check to be 290 ml.

As the increment of pressure is from atmospheric up to the desired test value, the gage pressure as determined by the dead-weight tester represents Δp in Equation [2].

DESCRIPTION OF APPARATUS AND DETAILS

A thick-walled, cylindrical, steel pressure vessel A in Fig. 3 ($5\frac{1}{4}$ in. OD and 2 in. ID) was machined with the top of the cylinder containing an annular slot C or mortise of rectangular cross section to act as part of the seal for the test fluid. The inside bottom of the cap B was machined as a cone D of $2\frac{3}{4}$ in. diam with an annular V-shaped tenon E machined to fit into the mortise of the cylinder without the tenon touching the upper corners of the mortise. Hard solder wire was cut, lapped, and placed within the mortise. The V-shaped tenon was forced into the solder by tightening six $\frac{3}{8}$ -in. stud bolts F , so that a perfect fluid seal was formed. The design causes all entrapped air or gas to be forced out through the vertex of the cone.

To introduce fluid under pressure into the vessel, measure its temperature, and discharge compressed fluid upon release of pressure, suitable threaded adapters G with copper gaskets were fitted into the top of the cap with small holes extending through the cap into the pressure chamber. The small thermometer well H of stainless steel to contain thermocouple wire was first press-fitted into the cap.

A $\frac{1}{8}$ -in. steel needle valve I was screwed into the inlet adapter, and a second valve J was fitted to the relief adapter. At the top of the discharge valve there was fitted a metal-to-glass adapter, machined and ground with a tapered hole to fit precisely the male end of a standard ground-glass Pyrex tube.

Fig. 4 shows the general arrangement of the apparatus. The test vessel is mounted within a steel-encased water bath having

FIG. 3 CROSS SECTION OF TEST VESSEL—NORTHWESTERN UNIVERSITY

FIG. 4 ASSEMBLY OF BULK-MODULUS TEST APPARATUS AT NORTHWESTERN UNIVERSITY

inlet water and drainage connections. A 750-watt immersion heater and thermoregulator controlled the water-bath temperature. A potentiometer was connected to iron-to-constantan thermocouple leads inserted in the temperature well.

To segregate the test fluid from the fluid in the dead-weight gage tester, the inlet valve to the pressure chamber was connected by $1/8$ -in. pressure-transmission pipes to a U-tube-type mercury piston, one leg of which was a 2000-psi pressure chamber sight-gage glass, and the other leg a machined steel cylinder connected to a 5000-psi dead-weight-gage tester. Valves were used at high points of the transmission piping to release all gases or air from the system.

Three standard calibrated microburettes with Pyrex tapered adapters of 2.0, 3.0, and 5.0 ml capacity, each reading to 0.01 ml, were used to determine fluid-volume displacement from the test vessel.

In addition, the glassblower made from carefully matched serological pipettes, three other microburettes as follows: One of 0.2 ml capacity from two 0.1 ml; another of 0.4 ml capacity from two 0.2 ml; and a third of 2.0 ml capacity from two 1.0 ml. All were graduated to 0.01 ml and can be easily read to 0.001 ml. These small-capacity burettes give great accuracy in determining small volume changes as a 0.01 ml displacement causes a $5/8$ -in. rise in fluid level in the smallest-diameter burette. Calibrations of all burettes were checked by volume with mercury.

Tests proved the steel valves and pressure-transmission pipes were absolutely tight. One characteristic of all dead-weight testers is that continuous rotation of the piston is necessary and that after a 30-min period, some oil from the tester slips by the piston up into the surrounding cylinder, requiring adjustment of the handwheel to maintain weights and pan at constant level. This in no way affects the magnitude of unit pressure exerted on

the mercury piston in Fig. 4, as long as the pan is not allowed to rest on top of the fixed cylinder.

ESTIMATED ACCURACY

Using the Lamé formula as corrected by Clavarino for the determination of tangential and radial unit stresses in a thick-walled hollow cylinder under internal pressure only, theory indicates that the maximum change in total volume of the test vessel of 0.0043 per cent would be practically negligible between 25 and 1500 psi maximum internal pressure.

However, the opening of the gap between the cap and cylinder at the seal needed investigation. Seven SR-4 electric strain gages were fastened to the test vessel, in such positions that radial tangential deformations and opening of the gap were determined, in microinches per inch. According to theory, radial and tangential stresses are zero at the outside surface of the vessel, and the tests confirmed this.

At 1500 psi there is 885 lb of pull on each of the six bolts of the cap, or 16,500 psi stress in the shank, and the seal never leaked. The average increase in measured opening of the gap was 225 millionths of an inch. This is a displacement of the contents of the test vessel (290 ml) of 0.0108 ml, or 0.0037 per cent. The total calculated change in volume of the test vessel caused by all stresses is about 0.008 per cent or 0.79 per cent of the volumetric displacement in the microburette, based upon test results with gasoline.

To be sure that the test vessel could be used without placing the vessel within an equalizing pressure chamber as would be essential for higher working pressures, confirmatory tests, described in detail later in this paper, were run to check values on the bulk modulus of distilled water free from dissolved oxygen as reported by other investigators. The values of the modulus

for water came within the range of values determined by others. It is believed this new test device can be used to obtain bulk moduli with errors not exceeding 2 per cent on any liquid during an individual run at the highest test pressure which is 1500 psi.

TEST PROCEDURE

Fig. 5 shows the apparatus under simulated test conditions. Before undertaking a series of runs, the test vessel is thoroughly cleaned with carbon tetrachloride, and the lower portion of the cylinder filled with the fluid to be tested. A dry rag is used to wipe a thin film of mercury onto the surface of the V-shaped lead seal. The cap is connected to the cylinder tightly so as to withstand 2000 psi, and the remainder of the cylinder and conical dome is filled with fluid. The vessel is placed in the water bath, and transmission pipes are connected as in Fig. 4. The fluid and the test chamber are brought to uniform test temperature using either ice or heated water. It may take 30 min or more before the temperature levels off, and during this time the fluid temperature is read by the potentiometer.

Mercury is placed in the bottom of the U-tube, and pipes connecting the leg to the test vessel are filled with fluid. A medium-weight lubricating oil is used in the dead-weight tester, the connecting piping, and the leg of the U-tube away from the test vessel.

A pressure of a few pounds is placed on the system. Bleeder valves are opened to flush out all entrained air or gases and are then closed. One of the calibrated pipettes of suitable volume for the estimated displacement of test fluid is selected. The ground tapered joint is greased with a solvent-resistant stopcock grease and is heated slightly before the taper is pushed into the adapter. The fluid content of the test vessel is then placed under atmospheric pressure with the burette always open at its top.

With inlet and discharge needle valves *I* and *J* open, a slight pressure by dead-weight tester is exerted on the oil, which is

forced against the mercury U-tube, and the same pressure is transmitted by displacement of this mercury piston to the fluid in the test vessel. The test fluid rises into graduated section of the microburette for a first reading at atmospheric pressure.

Upon closure of the discharge valve a small quantity of fluid is displaced upward which increases the first reading of fluid in the burette to the exact initial value used in the test data. Opening of the valve causes a lowering of fluid in the burette equal to the quantity displaced by movement of the valve needle. The required number of weights are placed on the pan of the tester. Pressure is then applied through the tester until the pan connected to the piston of the tester is elevated about $\frac{3}{4}$ in. above the surrounding cylinder. Weights, pan, and piston are spun continuously during application of pressure to the system. The Bourdon gage is used only as an indication of the unit pressure, to keep the operator from raising the tester piston too high and forcing it out of the cylinder.

As the desired unit pressure is reached, the inlet valve is closed uniformly at a very slow rate. Unit pressure is thus locked within the test vessel. The discharge valve *J* is opened slowly, and the quantity of fluid compressed from atmospheric pressure to the applied higher test pressure is permitted to expand into the burette at atmospheric pressure to an approximate final reading. The discharge valve is then closed slowly to eliminate all error due to the volume displaced by the valve needle. The ultimate rise of fluid in the burette, as read with a magnifying glass, is taken as the true final reading. The difference between the true initial and final readings is the change in volume (ΔV) of Equation [2] caused by re-expansion of the fluid from the test pressure to atmospheric pressure.

Providing there is sufficient volume of fluid above the mercury leg of the piston, the final reading of the burette can become the initial reading for a second test. The burette need not be re-

FIG. 5 TEST APPARATUS IN OPERATION

moved for cleaning until such time as the total calibrated length has been wet by the fluid. A strong Alkonox and distilled-water cleaning solution is used at about 200 F to wash test fluids from the inside of the burettes. Burettes are flushed with distilled water and dried by compressed air prior to regreasing the outside of the taper and continued use. Before the mercury in the U-tube is driven past the invert, the bleeder valve *K*, Fig. 4, is opened to atmospheric pressure. Test fluid is poured into the pipe system, and the necessary quantity of oil is removed from the dead-weight tester. Time is then allowed for the fluid in the test vessel again to arrive at the desired test temperature before further runs are made.

COMPARISON WITH PREVIOUS INVESTIGATIONS ON WATER

The experimental techniques were first worked out by preliminary runs on crude oil. These tests were then made on boiled distilled water at 68 F to check the characteristics and behavior of the apparatus on a liquid for which considerable experimental results are available on compressibility at 1 atm and at pressures above 300 psi.

Figs. 6(a and b) show the Northwestern test results, as compared with data reported by thirteen former experimenters. In

experimenters mentioned. Above 50 psi the modulus increases rapidly, until a value of about 300,000 psi is obtained in the neighborhood of 300 psi. Fig. 6(b) shows an enlarged portion of the modulus-pressure curve in the lower pressure range.

It is concluded from a careful study of the runs on distilled water, that the accuracy of the test vessel and appurtenances, and the techniques used in the Northwestern tests are comparable to that obtained with various devices or apparatus of former experimenters. This verification is important as almost all experimenters since Amagat have checked the performance of their test apparatus with distilled water as free from dissolved oxygen as is possible of attainment.

For most work on water hammer at ordinary pipe-line pressures, it is evident that a modulus of 300,000 psi for water is a valid unit, although some engineers use 294,000 and others 310,000 psi. If 300,000 psi is used and 30,000,000 psi as Young's modulus for steel in tension, the ratio of 1/10 in the formula for calculation of the speed of propagation of the water-hammer pressure wave is within experimental error. At ordinary pipe-line pressures, computations are simplified somewhat which is probably the reason for the widely adopted value of about 300,000 psi, plus or minus 3 per cent for bulk modulus of water.

FIG. 6(a) TEST RESULTS ON BULK MODULUS OF WATER BY VARIOUS EXPERIMENTERS

some instances Equation [2] could be used directly, and in others the bulk modulus was computed as the reciprocal of the compressibility C , where C is expressed in atmospheric units, that is, the ratio of the decrease in volume per atmosphere of pressure to the volume of the liquid.

Tyrer (2) worked at 1 and 2 atm only, Amagat (5), Bridgman (5), Parsons and Cook (7), and Jessup (8) give results at 1 atm, in addition to higher pressures, none of which, however, were below 300 psi. All experimenters appeared to be interested primarily in the compressibility of water at high pressures. In most instances, where the experimenters plot data obtained at pressures above 700 psi, they extrapolate the compressibility curve as a straight line into the low-pressure range, assuming the compressibility to be independent of the change in pressure.

Parsons and Cook (7), however, are very definite in showing that water has a bulk modulus of 200,000 psi at atmospheric pressure and 4 C, and a modulus of 400,000 psi at 2000 atm. Wherein this great change takes place is not shown. Northwestern tests show that the modulus is about 200,000 psi at pressure of 25 to 50 psi which is in general agreement with the

FIG. 6(b) ENLARGEMENT OF FIG. 6(a) FROM 0-1100 PSI

RESULTS ON CRUDE OILS AND GASOLINE

Figs. 7(a, b, and c) show the plotting of test results and the curves established for the two crude oils and gasoline samples taken from the test pipe sections of the field tests utilized by the Joint Surge Conference (13). Samples of 10 gal were shipped in fluid-tight metal containers to the Northwestern Technological Institute Hydraulic Laboratories for these independent bulk-modulus tests. Fig. 8 shows similar test results on G.H. No. 3 crude oil shipped from the Kuwait oil fields on the Persian Gulf.

Four temperatures, 32, 60, 100, and 130 F, were maintained for each of the pressure series for the three crude oils, but the 130 F temperature was not used in the gasoline tests. These temperatures cover the climatic and operating ranges usually experienced in oil-pipe-line work, as well as any appreciable rise in temperature caused by pipe friction. The range in pressure varied from 25 to 1500 psi, which covers the usual operating pressures of oil pipe lines.

At any given pressure the variation of bulk modulus or compressibility with temperature is pronounced. This has been found by all experimenters. No general conclusion can be reached as to the degree of variation with temperature, but in general the three crude oils and the tested gasoline seem to decrease roughly about 700 psi in bulk modulus for each degree Fahrenheit increase in temperature.

Gasoline, Fig. 7(c), at pressures above 200 psi and up to 1500 psi had a relatively insignificant change in modulus with increase in pressure. Below 200 psi, the change in modulus is more pronounced.

The crudes, Figs. 7(a) and (b), show that above 1000 psi the modulus remains about constant in value for any given temperature. Below 1000 psi, the modulus decreases in some degree as the pressure decreases, and below 400 psi the modulus decreases quite rapidly in some cases. Between 400 and 50 psi at 60 F, the McCamey crude shows a drop of 62,000 psi or 25 per cent; Wink-Monahans crude shows a decrease of 25,000 psi or 12 per cent; Kuwait crude, Fig. 8, shows a decrease of 53,000 or 23 per cent.

Fig. 9 shows a plot of variation of bulk modulus with temperature at a pressure of 1000 psi for the four samples tested. Until considerable additional information is available, it appears evident that petroleum products cannot be tested at just one temperature and a satisfactory conclusion arrived at for the bulk modulus at any other temperatures. In studying the test data of other experimenters, it was impossible, in most instances, to determine the compressibility or bulk modulus at temperatures other than within the range of the test. Water at 1 atm of pressure when tested by four experimenters shows that variation with temperature follows no well-defined law.

COMPARISON OF MEAN COMPRESSIBILITIES OF SAMPLES TESTED WITH WORK OF OTHERS

The test values of bulk modulus in the Northwestern tests were computed also in terms of mean compressibility in per cent from zero to 1000 psi in order to compare results with the study in the American Petroleum Institute progress report made by Jacobson (9). Values are plotted relative to API gravity at 60 F in all cases, Fig. 10. Undoubtedly, other factors than specific gravity modify this simple relationship. Viscosity is one factor as is shown by Matteson (14), where he uses the Cragoe modulus to extrapolate test data on compressibility of oils at 711 psi to values at higher pressures. The authors interpreted the data by Jacobson, et al (9), somewhat differently, and the solid-line curve shows their estimate of the reported test values. An assumed curve has been drawn for 60 F as no data existed for this temperature.

The graphical studies, Fig. 10, show close agreement between the test data used by Jacobson and the Northwestern test data at

FIGS. 7 AND 8 NORTHWESTERN UNIVERSITY TEST RESULTS ON CRUDE OILS AND GASOLINE

the higher pressure. A possible hazard exists in using data plotted in this way, because a small change in per cent compressibility means a much more significant change in the numerical value of the bulk modulus and a consequent error in the surge-wave velocity computation.

COMPARISON OF BULK MODULUS VALUES WITH WORK OF OTHERS

Fig. 11 shows a comparison of the Northwestern test data at about the median of test pressures with actual test data at 32 F and 60 F determined by other investigators. Library research disclosed that very few tests exist at lower pressures. A few tests have been found with a temperature gap as large as from 32 F to 167 F. Gravity in degrees API at 60 F is used as abscissas, as in Fig. 10, but the ordinate is the bulk modulus instead of per cent compressibility. Several experimenters used 50 kg per sq cm or 711 psi, which is the reason for selecting this apparently odd pressure value. Only the temperatures shown could be used, as these were the reported results, and no interpolation or extrapolation of test data is resorted to in the figure.

FIG. 9 VARIATION OF BULK MODULUS WITH TEMPERATURE AT 1000 PSI

Fig. 11 shows the apparent variation in bulk modulus with API gravity in a more useful light for liquid-hammer purposes than if per cent compressibility is used. It also gives an opportunity to include a few more test-data points than are shown by Jacobson (9). Curves drawn by the authors indicate that the Northwestern tests are in general agreement with the results by others, but a considerable variation in bulk modulus for a given API gravity is manifest. The graphs indicated to the authors that further investigations are needed in order to arrive at more definite conclusions as to the variation of bulk modulus with specific gravity. By interpolation and extrapolation of existing data with some risk as to accuracy of the conclusions, it is possible to show a relationship between values of bulk modulus of petroleum products and API gravity. Unfortunately, in order to do this, data must be used at pressures substantially above usual pipe-line pressures.

Fig. 12 is similar in scope to Fig. 11, but shows the Northwestern test results at a pressure of 1000 psi for 80 F and at 100 F, compared with the results by others. The points shown are in some cases actual test-data points, but in other cases they are points obtained either by interpolation or extrapolation of actual test data.

The solid-line curves in Fig. 12 are obtained from Jacobson (9), who used data by Jessup (8), Sage and Lacey, et al (12), to determine first the shape of the curve at 1000 psi and 100 F. This made it possible to determine the trend of the curves shown in Figs. 10, 11, and 12, at temperatures where only meager data are available. It appears from these comparisons that Jacobson's curves represent the "minimum" bulk-modulus values for API gravities at 60 F. The dashed-line curves drawn by the authors represent their estimate of an "average" determination of the relation of modulus to API gravity. The dot-and-dash curves show the "maximum" envelope of existing data.

DISCUSSION OF CURVES

Fig. 12 indicates that for petroleum products under a pressure of

1000 psi and with gravity above 90 API, the bulk modulus is a fairly well-defined value.

As the API gravity decreases below that of gasoline at about 60, variation in bulk modulus from the Jacobson curve is more pronounced. When the lower range in gravity is reached, in the neighborhood of the crude oils at API gravity of about 35, the variation is more significant. Fig. 11 shows that the foregoing statements are probably correct for pressures as low as 700 psi, although at that pressure no test data could be found by the authors on products having a gravity greater than 75 deg API. At the lower pressures, the variation in bulk modulus with pressure is even more significant, as shown in Figs. 7 and 8.

COMPARISON WITH FIELD RESULTS

In the field-test program carried out by the Joint Surge Conference, the actual velocity of the pressure wave could be determined, based on the synchronized pressure time recordings at various points along the test sections. The accuracy of this measurement was probably on the order of 1 per cent to 2 per cent, depending on the particular location involved.

By taking the data on the McCamey crude plotted in Fig. 7(a) and interpolating between the 32 and 60 F curves, a 45 F curve can be obtained fairly accurately. This was the temperature existing during the field tests, and the bulk modulus versus pressure is shown as the solid line in Fig. 13(a). If the assumption is made that the compressibility is uniform from zero to 1000 psi or higher, then a line tangent to the curve between approximately 800 psi and 1500 psi can be extrapolated back to zero. This is shown as the broken line in Fig. 13(a). It is believed that this particular procedure has been used in many instances to secure the bulk modulus in the lower pressure ranges.

Table 1 shows the theoretical value of the velocity of the pressure wave, based upon the 45 F Northwestern curve, and that obtained from the extrapolated line. The measured values from the field tests are given for comparison.

FIG. 10 COMPARISON OF NORTHWESTERN TEST RESULTS ON COMPRESSIBILITY OF PETROLEUM PRODUCTS WITH RESULTS SHOWN BY JACOBSON, ET AL.

It will be seen that the calculated value on this basis, using the 45 F Northwestern curve, is 3980 fps based upon a mean value of k equal to 218,000 psi. Ten of the field tests were examined, and the average velocity of the pressure wave was found to be 3998 fps. The maximum value was 4090 fps and the minimum 3880 fps.

Applying this same procedure to the extrapolated curve, a mean value of 256,500 psi is obtained, or about 17.5 per cent higher than the Northwestern value. When this is used in the theoretical formula for the velocity of the pressure wave, a value of 4296 fps is obtained and is nearly 8 per cent higher than the average of the field tests.

Similar comparisons were made with the tests on the Wink-

Monahans crude, shown in Fig. 13(b), and the extrapolated curve, covering pumping tests, give a value about 2 to 3 per cent higher than would the Northwestern tests.

TABLE 1 COMPARISON WITH FIELD TESTS; MCGAMEY CRUDE AT 45 F

Line pressure, psi	Bulk modulus, Northwestern tests	Extrapolated line
125.....	212000	256000
150.....	218000	256500
175.....	223000	257000
Mean value k	218000	256500
Velocity of pressure wave a :		
Calculated	3980 fps	4296 fps
Test (avg of 10)	3998 fps	

FIG. 11 COMPARISON OF NORTHWESTERN TEST DATA WITH ACTUAL TEST DATA OF OTHER EXPERIMENTERS AT 711 PSI AND AT 32 F AND 60 F

In the Plantation series the curves shown in Fig. 13(c) were obtained on gasoline at 72 F. In this case the tests in the field indicated a velocity of 3620 fps with a calculated value from the Northwestern tests of 3590 fps as compared with 3640 fps using the extrapolated curve.

It is evident that there is considerable variation from crude to crude and between crudes and refined products in the relationship between bulk modulus and pressure at a constant temperature. Where these curves do not depart by more than 5 per cent at the low pressures, an error in the velocity of the pressure wave can be quite small, probably on the order of 2 to 3 per cent.

In the case of the McCamey crude, however, the difference in the weighted mean of the bulk-modulus value was over 17 per cent and the calculated value, using this figure, is 7 to 8 per cent higher than that measured in the field.

Fig. 8 shows the results of the tests on a crude from the Middle East, and it will be noted that this material behaves more nearly like the McCamey crude and thus the possible error in determining the velocity of the pressure wave and the magnitude of surges, as well as the damping of surges would be appreciable.

CONCLUSIONS

In any surge investigation where an accuracy closer than 5 per cent is desired, in the determination of maximum surge pressures

and the degree of damping of waves, it would be highly desirable to determine experimentally the bulk modulus of the material or materials to be transported in the line.

This is particularly desirable when there is a substantial variation in temperature, as well as variations in pressure in the system, so that such effects can be taken into account in any investigation.

The means of obtaining bulk-modulus data has been greatly simplified through the use of the apparatus described in this paper, and results can be made available in a matter of a few days after a sample has been received at the laboratory.

Where there are large investments in pipe lines and particularly when low factors of safety are used in the design, it would seem highly desirable to know the bulk-modulus data in addition to the usual information concerning specific gravity, and viscosity variations with temperature, and thus provide a more accurate basis of design than if pure assumptions from meager data are relied upon.

Discussion

JOHN W. DASHIELL, JR.⁵ In this paper Equation (1) might be easier to follow if written

$$a = \frac{12}{\left[\frac{w}{g} \left(\frac{1}{k} + \frac{d}{Ee} \right) \right]^{1/2}}$$

Equation [2] has an error in definition of symbols

$$K = \frac{\Delta p}{\Delta v} V$$

where Δp = pressure increment in psi

Δv = volume decrement produced by pressure increment Δp .

Figs. 7 (a, b, c) and 8 show an unexplained sudden decrease in bulk modulus as the pressure is lowered below 100 or 200 psi. Since the compressibility is the reciprocal of the bulk modulus, this would show a sudden increase in compressibility as the pressure is lowered below 100 to 200 psi. It suggests the presence of entrained air or gas coming out of solution as the pressure is reduced.

Reference to the literature shows the compressibility of a wide variety of liquids including oils to vary directly with the temperature and inversely with the pressure but it is difficult to explain any sudden deviation from a smooth curve as shown in the aforementioned figures since these curves show the bulk modulus to be approaching zero at zero pressure. This would mean that the compressibility becomes infinite at zero pressure (gage)—a condition that is exemplified by a perfect vacuum.

Measurement of Temperatures in High-Velocity Steam¹

By J. W. MURDOCK² AND E. F. FLOCK³

The demand for more accurate values of thermal efficiencies in modern steam power plants, together with the fact that the velocity of steam is often so high that the impact effect upon temperature-measuring instruments can no longer be neglected, has created a need for improved temperature instrumentation. Studies have been made of the performance, in moving air and steam, of various total-temperature-type wells suitable for use in steam at operating conditions. The instruments recommended for such applications, constructed so that the sensing element is surrounded by nearly stagnant steam, have temperature-recovery factors above 0.9, which do not change significantly with either the medium, its temperature, or its pressure. Although additional work remains to be done on reducing their sensitivity to flow direction and pattern, these wells, when installed in straight pipes through which steam is flowing at any velocity up to 725 fps, yield total enthalpies which are accurate to within 1 Btu per lb.

NOMENCLATURE

The following nomenclature is used in the paper:

- T = temperature, deg F or deg R
- p = pressure, psia
- v = specific volume, cu ft per lb
- u = internal energy, Btu per lb
- h = enthalpy, Btu per lb
- c_p = heat capacity at constant pressure, Btu/lb deg F
- G = mass velocity, lb/sec ft²
- V = velocity = Gv , fps
- M = Mach number
- δh = heat leak between specified stations, Btu per lb
- r = recovery factor
- θ = angle of attack
- g = acceleration of gravity, ft/sec²
- R = universal gas constant, Btu/lb deg F
- J = mechanical equivalent of heat, Btu/ft lb
- $A = 1/J$, ft lb/Btu

The subscripts s , t , and i mean static, total, and indicated, respectively.

INTRODUCTION

Normal progress toward more compact and more efficient power plants involves the handling and utilization of the working

medium at ever higher temperatures, pressures, and velocities. Simultaneously with this trend toward more severe operating conditions there is a demand for increased accuracy in values of efficiency determined experimentally. This in turn requires a better knowledge of the state of the steam at various locations throughout the power plant, which can be obtained only with improved instruments and methods of measurement.

Recognizing these facts, the Bureau of Ships is sponsoring a co-operative program of research and development at the Naval Boiler and Turbine Laboratory and at the National Bureau of Standards, aiming primarily to develop and evaluate more accurate instruments for measuring pressure, temperature, and rates of flow in steam systems. The present paper is restricted to a description of progress made to date on the measurement of steam temperatures.

The three primary sources of error in the measurement of the temperature of a flowing gas are radiation, conduction, and the effect of impact due to directed motion. In steam systems, proper insulation of pipe walls causes their temperature to approximate that of the steam and makes the loss of heat from the temperature-sensing element by radiation and conduction negligible, provided the instrument is designed properly. Thus the principal element of uncertainty, so far as most applications in steam are concerned, is the impact effect.

This effect in a flowing gas is of practical importance only when the directed velocity of the gas becomes appreciable in comparison with the mean velocity of random molecular motion. Thus, so long as steam velocities were low, there was no impact problem. However, velocities now used and those contemplated in future power plants are so high that the impact effect upon temperature-sensing devices no longer can be neglected. This becomes more apparent when it is recalled that such devices as thermocouples and resistance thermometers, either exposed directly to moving gas or sheathed in protective wells, respond only to the translational energy of the gas molecules.

THERMODYNAMIC CONSIDERATIONS

Consider that a compressed gas is allowed to expand adiabatically from a large reservoir in which its velocity is nearly zero, through a nozzle to the atmosphere. The adjective "total" and the subscript t are used to describe the quiescent state of the gas in the reservoir, while the properties of the moving gas, as they would appear to an observer moving with the gas and to whom the gas would appear to be static, are described by the adjective "static" and indicated by the subscript s .

For the adiabatic acceleration of the gas passing through the nozzle, and for the reverse process of deceleration as well, conservation of energy requires that

$$u_t + Ap_t v_t = u_s + Ap_s v_s + V^2/2gJ \dots \dots \dots [1]$$

This relation holds, even in the presence of such irreversible phenomena as friction and shock waves, which influence the distribution of energy among the three terms on the right, but not their sum.

By the definition of enthalpy, this equation can be written in the form

$$h_t = h_s + V^2/2gJ \dots \dots \dots [2]$$

which introduces the concept of two kinds of enthalpy, namely, a total enthalpy characteristic of the stagnant gas, and a static enthalpy characteristic of the moving gas, the latter being its enthalpy as it would appear to an observer moving with the gas. Obviously, it is the total enthalpy which is of interest in evaluating thermal efficiency, since this includes the kinetic energy of directed motion, along with the more familiar form characterized by temperature and pressure alone. In the adiabatic process being considered, the total enthalpy of the gas remains constant, without regard to reversibility or deviations from the perfect-gas law.

Dividing both sides of Equation [2] by c_p , which is now assumed to be independent of temperature as is the case for a perfect gas, gives

$$T_t - T_s = V^2/2gc_p \quad [3]$$

This introduces the concepts of total and static temperature, coordinate with the afore-mentioned concepts of enthalpy. Again, the total temperature is the temperature of the gas at rest, while the static temperature is that which would be indicated by an instrument moving in the same direction and at the same velocity as the gas. The two are identical in quiescent gas, but differ from one another in a moving gas, directly as the square of the velocity, and inversely as the heat capacity at constant pressure.

When a perfect gas is subjected to an adiabatic expansion of the type being considered, not only the total enthalpy but also the total temperature remains constant. However, in an adiabatic expansion of an actual gas there is usually a small change in total temperature, and such changes were observed in the present work with steam.

Obviously, it is impracticable to measure T_t directly in a moving gas. However, if an instrument designed to stop the gas adiabatically and reversibly is inserted in the stream, a temperature-sensing element located in the gas so brought to rest will indicate its total temperature. This total temperature, together with the total pressure of the stagnant gas, suffices to establish the total enthalpy of any actual gas for which tables of these properties exist.

When any device other than an idealized total-temperature probe is inserted in flowing gas, it will attain a temperature T_i intermediate between T_t and T_s , because only part of the gas impinging upon it is brought completely to rest. That part of the kinetic energy of directed motion which is converted to heat upon impact raises the temperature of the device above T_s . Friction in the boundary layer of gas around the device also makes a contribution in this same direction, so that the amount of the increase

is a function of the configuration of the device and of the rate and pattern of the flow in its immediate vicinity.

For accurate interpretation of the temperature indicated by an instrument located in a stream of high-velocity gas, the relative position of T_i with respect to T_t and T_s must be known. It is common practice to specify this position in terms of recovery factor r , defined as

$$r = (T_i - T_s)/(T_t - T_s) \quad [4]$$

These temperature relations, as influenced by velocity, are illustrated in Fig. 1 which shows the temperature which would be indicated by instruments having recovery factors of unity, 0.93, 0.65, and zero, if they were immersed in steam at various velocities, but always having a total temperature of 800 F, and a heat capacity at constant pressure of 0.5 Btu per lb deg F. These particular recovery factors were chosen for illustration because the value 0.93 is typical of the wells to be described later, and 0.65 is typical of a bare thermocouple junction.

DEVELOPMENT OF INSTRUMENTS

Characteristics Desired. The obvious advantages of using an instrument with a recovery factor close to unity are that the indicated temperature may often be taken as the total temperature, and that, in cases where higher accuracy than this is required, the small difference between T_t and T_i can be computed with ample accuracy from an approximate value of r . Stated in another way, the higher the value of recovery factor, the less is the practical importance of its actual value and of the effects of the operating variables upon it.

Instruments of the total-temperature type^{4,5} have been developed to a high degree for use primarily in high-velocity air streams such as are encountered in wind tunnels and in flight. However, these do not lend themselves to direct application in machinery containing steam at high temperatures, pressures, and velocities for the following reasons:

- 1 They are relatively large and might therefore block off more of the flow passage than is tolerable.
- 2 They would have to be made very sturdy to withstand the impact and mechanical vibrations to which they would be subjected in steam systems.
- 3 They are sensitive to the direction of flow, which may be unknown or variable within a machine.
- 4 It would be difficult to provide a pressure seal which is effective at high temperatures and yet allows ready replacement of the temperature-sensing element either during or between runs.

Instead of attempting to adapt existing devices for service in steam, it was considered more practical to develop a modification which would approximate their performance, yet be free of some of their disadvantages and possess some distinct advantages over instruments designed for other applications.

The temperatures of interest in steam systems are within the range of satisfactory performance of base-metal thermocouples, which are sufficiently accurate for the intended purpose when well-established techniques⁶ are followed. There is much to recommend the use of thermocouples in this application, for example, low cost, small size permitting measurements in a limited region

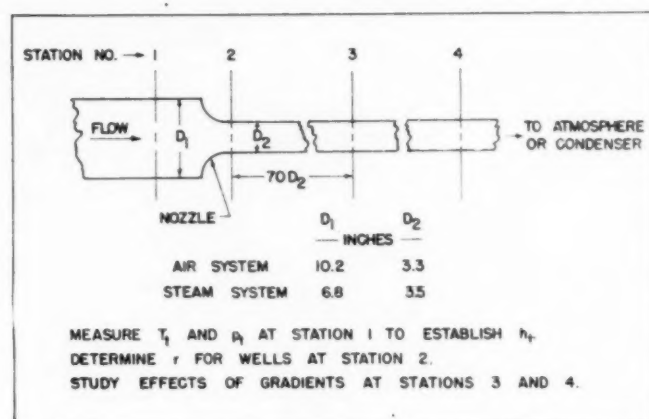

FIG. 2 SCHEMATIC DIAGRAM OF TEST SYSTEMS

as well as surveys of gradients, ruggedness, simplicity of construction and installation, rapid response to changes in temperature, and availability of indicating and recording devices which are accurate, simple to operate, and highly reliable. Therefore effort was concentrated on devices employing thermocouples as sensing elements, although the wells to be described may also be used with resistance thermometers.

Because it seemed unwise for many reasons to expose thermoelements directly to steam, the development of appropriate wells was desirable. From the thermal standpoint, the inner tube of such a well should be small and thin to promote rapid response of the measuring junction and to reduce heat loss along solid parts. If the unit is to have a high recovery factor, the inner tube must be surrounded by steam which has been brought as closely as practicable to stagnation. In addition, considerable mechanical strength is required, particularly resistance to vibration. It is highly desirable that, in case the more fragile parts should break, they be retained and prevented from passing through and damaging parts of the machinery.

The remainder of this paper describes the development of wells to meet these requirements and the results to date of studies of their performance in streams of air and of steam contained in straight pipes.

General Description of Equipment. For reasons of speed and economy, preliminary studies of the performance of wells were made in streams of air. These results were used in selecting the more promising instruments for evaluation in steam under operating conditions.

The test systems using air and steam were essentially the same. In both, the test medium was accelerated from a low velocity in a pipe of large diameter by passage through an efficient nozzle. Fig. 2 is a schematic diagram representing both systems.

The state of the medium was established accurately by measuring its temperature and pressure at station 1, in a region of low velocity. For determinations of recovery factor, the test instruments were placed in the stream at station 2 in the throat of the nozzle, where there were no significant gradients in temperature or velocity. Similar instruments also were located at stations 3 and 4. For the steam system, only those results obtained at stations 2 and 4 are presented here, because the flow pattern at station 3 was not well enough known.

Glass-insulated duplex iron-constantan thermocouples were used with both test media. The stock of wire was calibrated at frequent intervals along its length, and the thermoelectric properties were found to be sufficiently uniform that a single calibra-

tion could be used for all thermocouples in any one installation. The basic temperature of the medium was observed at station 1, and the temperatures at other stations were determined by measuring differences therefrom. Thermoelectromotive forces were measured with Brown Elektronik self-balancing potentiometer indicators, graduated to 2 microvolts, and read by estimate to the nearest microvolt. In all measurements the reference junctions were maintained at 32 F in a slush of ice. In view of the precautions taken, the probable error in a single observed value of temperature difference is believed to be ± 0.1 F or less. This estimate includes only the error in determining the temperature of the measuring junction and not that due to any difference in temperature between this junction and the medium.

Results Obtained With Air. The first tests of temperature probes were made in an air system consisting essentially of a 4000-cfm blower discharging into a 12-ft length of 10-in. pipe, thence through a nozzle having a throat diameter of 3.25 in., a diffuser with a 7-deg included angle, and into the atmosphere. This equipment is shown diagrammatically in Fig. 3. The thermocouple wells were mounted singly in the throat of the nozzle in the region of uniform velocity, and the performance of each type was evaluated in terms of recovery factor as a function of velocity or Mach number (M).

At velocities above 700 fps ($M = 0.63$), local shock waves were formed, and the observed values of recovery factor became erratic. By increasing the temperature of the air so that the dew point was not reached in the nozzle, it was demonstrated that the observed scattering was not due to condensation shocks. Therefore a similar phenomenon is to be expected in steam, but only at higher velocities, since the temperature and hence also the velocity of sound in steam is usually higher.

In later tests with air, the blower was replaced by a centrifugal compressor, and a long run of straight tubing was substituted for the exit diffuser in Fig. 3. No thermal insulation was used in either arrangement since the inlet air was only slightly warmer than the atmosphere. In both systems the loss of heat between stations 1 and 2 was negligible. However, there was sufficient heat leak between station 1 and those 50 or more diameters downstream to make the observed temperatures unreliable, so that this work must be repeated.

The nozzle used with air had been calibrated previously so that the rates of air flow could be determined from measurements of the drop in pressure across the nozzle.

In the early stages of this program the recovery factors of the following simple devices were determined: cup-type total-tem-

FIG. 3 DIAGRAM OF AIR SYSTEM

FIG. 4 RECOVERY FACTORS OF SIMPLE DEVICES

perature probes, bare junctions, cylindrical wells of various diameters, and wells of elliptical and teardrop cross section. As will be seen in Fig. 4, all of these except the cup type have recovery factors lower than was desired.

The next step was the development of devices having protecting tubes concentric with inner wells, with openings in the upstream faces of the outer tubes to admit gas to the annulus. The inner wells, containing the measuring junctions, could thus be surrounded by stagnant gas. It is well known that the outer tube can be made to approach the total temperature of the gas more closely if some of the stagnant gas is bled downstream. It was found experimentally that the recovery factor of the unit was greatest when the area of the downstream or bleed holes was approximately one tenth that of the openings upstream. This area ratio was maintained in units made and tested subsequently.

Among the various wells tried, those which seemed most promising are illustrated in Fig. 5 and shown in more detail in Fig. 6. The bleed holes in Type A Fig. 5, are not visible because the central tube obscures them. Type A can be installed in odd-shaped spaces, and Type B is to be preferred for use in pipes and in spaces where support at both ends is possible. For con-

venience these types are designated as cantilever and fixed-beam wells, respectively.

The recovery factors of wells having the dimensions shown in Fig. 6, as determined in air, are shown in Fig. 7, with the curve for the cup-type junction repeated from Fig. 4 for comparison. It will be noted that the recovery factor of the fixed-beam well is higher than that of the cantilever well, and that it changes less with velocity. Thus the use of the former is recommended wherever its installation is practicable. Due to the support at both ends, this type can be made smaller and lighter for use in a stream of given Mach number. Therefore it will block less of the flow passage and be less subject to errors from conduction. The

FIG. 5 CANTILEVER AND FIXED-BEAM WELLS

stagnation pressure within the well can be transmitted through a connection at either end. It is to be noted that the inner well of either type will be retained in case of breakage.

With the second air system mentioned previously, wells were installed at stations 3 and 4 in regions of fully developed pipe turbulence. Average total pressures were determined by Pitot-tube traverses at the test stations, after which the test wells were substituted and measurements were made at the same flow rates. Wells with 5, 7, and 9 holes of the size and spacing shown as Type B in Fig. 6, were used. The 5 and 7-hole wells were identical with the 9-hole well, except for the omission of holes nearest the wall. Stagnation temperatures and pressures within the wells were measured, but because of heat loss only the latter are considered significant.

All three wells were found to develop stagnation pressures which are higher than the average total pressure of the turbulent stream. As might be expected from the known form of the velocity gradient, the 5-hole well, having holes only in the region of higher velocities, attains the higher stagnation pressure, and the 9-hole well is nearest to, but still above the average total pressure. It seems probable that a well of this type can be designed to attain the average total pressure more exactly, by proper location of the holes. Further investigations are planned.

Another item of practical interest with regard to wells of this type is the effect of angle of attack θ , since the direction of flow in certain test spaces may be both unknown and variable. The effect of direction of flow upon the stagnation pressure attained in the 5-hole well was determined at station 2, and corresponding tests were made with the 9-hole well in regions of fully developed turbulence. These results are shown in the lower curves, Fig. 8, in which the position indicated by 0 deg designates that the larger holes in the well were pointed directly upstream.

High sensitivity to angle of attack is undesirable, and some modification to reduce it seemed in order. To this end a $1/8$ -in. length of tube was soldered to each of the upstream holes of the

5-hole well, at an angle of 90 deg with the axis of the well. This unit, again tested in the nozzle, gave the results shown in the uppermost curve in Fig. 8. The marked decrease in sensitivity to angle of attack indicates the desirability of using the projecting

FIG. 7 RECOVERY FACTORS OF CANTILEVER AND FIXED-BEAM WELLS

FIG. 8 EFFECT OF ANGLE OF ATTACK ON PERFORMANCE OF FIXED-BEAM WELLS

FIG. 6 DETAILS OF CANTILEVER AND FIXED-BEAM WELLS

tubes in applications where the direction of flow is uncertain. No tests have been made in steam with this type of well.

Studies of the type described, obviously, should be made on a temperature as well as a pressure basis, and this will be undertaken in the near future.

EVALUATION OF FIXED-BEAM WELLS IN STEAM

Test Equipment and Method. To date the tests in steam have been confined to fixed-beam wells in a straight run of pipe. Using the system shown diagrammatically in Fig. 9, the basic conditions of the superheated steam at station 1 were varied over the following ranges: Temperature, 450 to 625 F; pressure, 20 to 200 psia; and flow rate, 10,000 to 30,000 lb per hr.

In a system having the dimensions indicated in Fig. 2, the maximum velocity attained in the throat of the nozzle (station 2) was about 725 fps. At station 4, the average velocity across the

section had a maximum value of approximately 1150 fps.

As indicated in Fig. 9, steam produced in a superheat-control boiler passed through an appropriate sharp-edged metering orifice, a control valve V_1 , and thence through a nozzle to the test station. After passing through a second control valve V_2 , it was condensed and led to one or the other of two tanks, which were weighed alternately every 3 min. The weighing-tank data were used in calibrating the metering orifice, the pressure drop across which could then be used as an accurate measure of the flow rate at any time of specific interest.

Steam pressures were observed with a combination of 16-in. suppressed-zero Bourdon gages and high-pressure mercury manometers used differentially. Static pressures were measured at each station with a Bourdon gage connected to a sharp-edged pressure tap located flush with the inner wall and about one pipe diameter upstream. At each station a manometer was used to measure the difference between the static pressure and that inside the well. Appropriate steam traps were installed at the level of the test system in all gage and manometer lines, and corrections were applied for the water columns to the instruments located approximately 15 ft below.

The measuring junction in each thermocouple well was located at the center of the pipe. However, a limited number of traverses showed no measurable difference in temperature over the central half-diameter.

The entire test system was lagged with 4 in. of insulation suitable for service under the conditions of these tests. At each operating temperature and flow rate, one or more runs were made at high pressure and low velocity, i.e., with valve V_1 , Fig. 9, open, and valve V_2 partially closed, in order to evaluate the heat leak through the lagging. In no instance was there a measurable loss between stations 1 and 2. The loss between stations 1 and 4 was between 0.1 and 0.4 Btu per lb, depending on the temperature and the flow rate. In making the calculations for each run, the value of h_1 at station 2 was considered identical with that at station 1, and the heat leak (δh) between stations 1 and 4 was subtracted from the value of h_1 at station 1 to get the prevailing value of h_1 at station 4.

In making a run, previously selected conditions were established in the boiler, and then in the test system by operating valves V_1 and V_2 . Observations were made only after a considerable time, in which a steady state was reached throughout

the test system and its insulation. Thereafter all temperatures and pressures were read in simultaneous cycles requiring about 2 min, until changes observed in three successive cycles were insignificant. The drop in pressure across the metering orifice was read periodically in the same interval, and the weight of condensate was determined every 3 min.

Results Obtained With Steam. A great many tests with steam were required to establish the characteristics of the thermocouple wells. However, a summary of the results can be made simple, because it was found that the performance of the fixed-beam wells does not change significantly with either temperature, pressure, or flow rate, except in so far as these characteristics influence velocity. Therefore the results may be presented as a function of velocity alone, as is done in Fig. 10, for wells having the form and dimensions shown in Figs. 5B and 6B. The filled and open circles apply to wells located at stations 2 and 4, in regions of uniform and nonuniform velocity, respectively. In Fig. 10A, differences in temperature are plotted against velocity, and the same results are shown on an enthalpy basis in Fig. 10B.

The total temperatures were calculated as follows: The value of h_2 can be obtained from the known values of h_1 , p_1 , and G , because Equation [2] and the relation

$$V = Gr_s \dots \dots \dots [5]$$

must hold simultaneously, and because h_2 and v_2 are dependent variables. In the mechanics of solving Equations [2] and [5], an equation relating h_2 and v_2 may be used as suggested by Keenan.⁷ Alternatively, advantage may be taken of the relation which is implicit in the steam tables, and h_2 may be calculated by successive approximations, as was done in computing the present results. Knowing h_2 and v_2 fixes the value of entropy, which in turn has the same value at the stagnant state. The latter is fully defined by the entropy and h_1 , so that the corresponding values of T_1 and p_1 may be read from the tables.

The indicated enthalpy h_1 is that found in steam tables for the observed values of temperature T_1 and pressure p_1 . Corrections for heat leak were applied only at station 4, as explained previously.

⁷ "Friction Coefficients for the Compressible Flow of Steam," by J. H. Keenan, *Journal of Applied Mechanics*, Trans. ASME, vol. 61, 1939, p. A-11.

FIG. 9 DIAGRAM OF STEAM SYSTEM

The most important fact demonstrated by Fig. 10 is that every experimental value of h_i at both test stations is within less than one enthalpy unit of the value of h_i determined at station 1. Thus the observed values of T_i and p_i , without any correction for recovery, establish values of enthalpy which are correct to within better than 1 Btu per lb at velocities up to 725 fps, for both uniform flow and the velocity gradient characteristic of fully developed pipe turbulence. Therefore wells of the type described are recommended without qualification for use in steam, since these will give more accurate values of enthalpy, without correction for imperfect recovery, than wells of any other type known to have been used in steam systems.

The results obtained directly from the wells, without correction for recovery, are of the accuracy specified only because the recovery factor is high. At first it might be thought that application of corrections based upon the known recovery factor would further reduce the error. This is correct if the well is located in a region of uniform velocity such as prevailed at station 2, as will be evident from the pattern of the filled circles in Fig. 10. These are all above the base line of zero error, and they show an upward trend with velocity. In fact, recovery factors calculated from these data are in excellent agreement with values obtained in air and shown in Fig. 7.

On the other hand, when the well is located in a region of fully developed pipe turbulence, as at station 4, application of corrections for recovery, as determined in the nozzle, would increase the accuracy of the final results in the range of lower velocities and decrease it at high velocities. This is apparent from the pattern of the open circles in Fig. 10 which show a downward trend with increasing velocity and fall below the base line at high velocities.

Corrections applied for imperfect recovery would lower all of the open circles and thus increase the errors of those points already below the base line.

To date the performance of the wells has been studied only in regions of uniform velocity and of velocity gradients characteristic of fully developed pipe turbulence. Neither of these flow patterns occurs frequently in operating steam systems, so that much experimental work remains to be done on the effects of upstream disturbances created by valves, strainers, bends, etc. However, the results of such studies will serve merely to evaluate corrections which are believed to be quite small, and the interim use of the wells without correction seems to be in order.

Problems Incident to Velocity Gradients in Steam. The problems incident to proper interpretation of results determined with wells located in regions where velocity gradients exist are believed to involve the nature of the sampling accomplished by the well, and the differences between steam and a perfect gas. Present results show that the net effect of these and the imperfect recovery is very small in regions of fully developed pipe turbulence. This may not be the case in the presence of velocity gradients of other types.

An analysis of the probable effects of velocity gradients is a desirable step in planning future experiments. Such a study has led to a plausible qualitative explanation of the apparent anomalies of Fig. 10, but its presentation here would require more

FIG. 10 PERFORMANCE OF FIXED-BEAM WELLS IN STEAM

space than is available. Hence this will be postponed, pending completion of additional experimental work.

In the course of future work in steam, it is hoped to study the performance of cantilever wells, to extend the present measurements to higher velocities, to measure the effects of upstream disturbances and angle of attack, and to determine the effectiveness of tubes projecting from the upstream openings in reducing the effects of the latter.

CONCLUSION

Meanwhile, the use of wells of this type in steam is recommended without qualification, since these will, without any correction for recovery, give more accurate values of enthalpy than wells of any other type known to have been used in steam systems. The fixed-beam wells described, when installed in straight pipes, yield directly values of temperature and pressure which establish the enthalpy of steam moving at velocities up to at least 725 fps with an error of less than 1 Btu per lb, regardless of whether the flow is uniform or characteristic of pipe turbulence.

Application of corrections for recovery of the wells reduces the remaining error in regions of uniform flow. However, the application of corrections determined in uniform flow to devices used in regions of nonuniform velocity may decrease the accuracy, so that, until more is known about the effects of gradients, it is considered wise to apply no corrections at all.

Additional studies to be made in both air and steam systems are expected to yield only minor improvements in the performance of the wells and in the interpretation of results obtained therewith. These improvements may be of practical importance where highest accuracy is essential, in which case the temperature, pressure, and flow instrumentation must be highly refined and used with great care. Otherwise, some single error in measurement may be greater than that due to imperfect recovery, thus making the application of small corrections for the latter entirely futile.

Relay Servomechanisms

The Shunt-Motor Servo With Inertia Load

By T. A. ROGERS¹ AND W. C. HURTY,² LOS ANGELES, CALIF.

This paper develops the theory of the shunt-motor relay servomechanism in terms of dimensionless motor parameters. Operating curves are drawn in the phase plane illustrating the effect of parameter changes on the stability of the servo for three forms of input signal. The first two forms of input signal, a step function and a uniform variation with time, have been discussed before and are included only for completeness. The third form of input signal, a sine function, is of most interest and is treated at greater length. The phase-plane curves, obtained from a differential analyzer, show three modes of operation which have been related to the servomechanism parameters by a relatively simple expression.

INTRODUCTION

RELAY servomechanisms have been used in several applications requiring high performance with a minimum of complex apparatus. The general methods of analysis given in this paper have been discussed by Hazen (1),³ MacColl (2), and Weiss (3) in earlier papers, and the application of the phase-plane diagram has been presented in some detail by Minorsky (4), and Andronow and Chaikin (5).

The usefulness of the phase-plane diagram would be greatly increased if the motor parameters were expressed in dimensionless quantities having a limited variation about a median value of unity. In order to fulfill the requirements of dimensionless parameters, the techniques used by the electrical engineer when working with power machinery will be employed. These ideas are not new but a review of the concepts may be in order.

All electrical machines have name plates stating those values of voltage, current, speed, power output, and frequency which the manufacturers consider as nominal when designing the machine. Values deviating from name-plate values may be expressed in actual values, per cent of rated values, or as a decimal ratio of the rated value. The decimal ratio has the advantage of being dimensionless and of entering directly into the computations without the decimal-point trouble introduced by the percentage notation. Since the decimal ratio of the existing value to the rated value has as its norm unity, instead of 100, it is called the "per unit value."

If, for example, a motor is operating at 90 volts instead of the rated 120 volts and draws 1.2 amp from the line instead of 1.5 amp as rated, then it is operating at 0.75 per unit voltage and 0.8 per unit line current. The usual abbreviation for per unit values is "pu."

PER UNIT MOTOR PARAMETERS

Direct-current motors are characterized by three physical relationships as follows:

1 The torque developed on the armature is proportional to the product of the armature current, and the magnetic flux entering the armature surface.

2 The voltage generated in the armature conductors, due to their motion in the magnetic field, as a consequence of rotation, is proportional to the product of the angular speed and the magnetic flux entering the armature surface.

3 The armature-circuit relations for a motor are such that the voltage applied to the armature is composed of two components, namely, (a) the armature-circuit resistance drop; and (b) the generated, or back voltage.

These three relationships may be expressed algebraically, for a shunt motor, as follows

$$M = K_1 I_a \Phi \text{ lb-ft.} \quad [1]$$

$$E_g = K_2 S \Phi \text{ volts} \quad [2]$$

$$E = E_g + I_a R_a \text{ volts} \quad [3]$$

where

M = developed torque, lb-ft

I_a = armature current, amp

Φ = useful or active magnetic flux, webers

E_g = generated or back voltage

S = armature speed, rpm

E = applied armature voltage, volts

R_a = total motor armature-circuit resistance, ohms

K_1, K_2 = constants of proportionality

Equations [1], [2], and [3] may be rewritten in terms of per-unit quantities by expressing all terms as ratios of the motor rated values. For the problem under investigation, the motor is considered to be operating at rated field flux corresponding to full voltage on the motor field

$$m = k_1 i_a \text{ (dimensionless)} \quad [4]$$

$$e_g = k_2 \frac{d\theta_0}{dt} \text{ (dimensionless)} \quad [5]$$

$$i_a = \frac{e - e_g}{r_a} \text{ (dimensionless)} \quad [6]$$

where

$$m = \text{per unit torque} = \frac{M}{M_r} = \frac{\text{developed torque}}{\text{rated torque}}$$

$$i_a = \text{per unit current} = \frac{I_a}{I_{ar}} = \frac{\text{operating armature current}}{\text{rated armature current}}$$

$$k_1 = \text{constant (dimensionless)}$$

$$e_g = \text{per unit generated voltage} = \frac{E_g}{E_r} = \frac{\text{generated voltage}}{\text{rated voltage}}$$

$$\theta_0 = \text{per unit angle} = \frac{\Theta_0}{\Theta_r} = \frac{\text{output angle}}{\text{rated angle}}$$

θ_r = rated angle by definition, "angle the motor passes through in 1 sec at rated angular velocity"

k_2 = constant — seconds

e = per unit applied voltage = $\frac{\text{applied voltage}}{\text{rated voltage}}$

r_a = per unit resistance
= $\frac{\text{Rated armature current in amperes} \times \text{armature resistance in ohms}}{\text{Rated voltage}}$

k_1 and k_2 should be determined from test data under operating conditions.

RELAY SERVO WITH INERTIA LOAD

A relay servo with an equivalent inertia load on the motor shaft may be represented as in Fig. 1.

FIG. 1 SCHEMATIC OF A RELAY SERVO

The electrical connections are arranged in such a manner that, for every input angle θ_i , the relays operate the motor to make θ_o approach the value of θ_i . The difference between these two values is called the error and is defined as

$$\varepsilon = \theta_i - \frac{\theta_o}{n} \text{ per unit}$$

The term ε_0 is one half the dead space between the relay operating points and is taken to be symmetrical about the point of zero error. There are, therefore, three conditions of motor operation; (a) full voltage on the motor armature in the forward direction, (b) the motor armature short-circuited for dynamic braking, and (c) full voltage on the motor in the reverse direction. The motor performance is described by a linear differential equation, for each of these conditions of operation, as derived from Equations [4], [5], and [6].

Substitute Equation [5] in [6] and the result in Equation [4] to obtain the equation for the per unit developed torque

$$m = \frac{k_1 e}{r_a} - \frac{k_1 k_2}{r_a} \frac{d\theta_o}{dt} \text{ (dimensionless)} \quad [7]$$

The developed torque is opposed by the inertia torque if windage and friction are neglected. Then

$$M = J \frac{d^2 \theta_o}{dt^2} \quad [8]$$

where

J = moment of inertia referred to motor shaft, (lb-ft sec²) units

Equation [8] must be corrected to dimensionless units by dividing by rated M_r and then converting the angle to per unit angle. The result is

$$m = \frac{J}{M_r} \theta_r \frac{d^2 \theta_o}{dt^2} \quad [9]$$

The combination of Equations [8] and [9] produce the equation of motion under conditions of a positive error greater than the dead zone

tion of motion under conditions of a positive error greater than the dead zone

$$\frac{J}{M_r} \theta_r \frac{d^2 \theta_o}{dt^2} + \frac{k_1 k_2}{r_a} \frac{d\theta_o}{dt} = \frac{k_1 e}{r_a} \text{ for } \varepsilon > \varepsilon_0 \dots [10]$$

In order that the relay servo be correctly described in its motion, there must be two more equations corresponding to the other zones of operation

$$\frac{J}{M_r} \theta_r \frac{d^2 \theta_o}{dt^2} + \frac{k_1 k_2}{r_a} \frac{d\theta_o}{dt} = 0 \text{ for } -\varepsilon_0 < \varepsilon < +\varepsilon_0 \dots [11]$$

and

$$\frac{J}{M_r} \theta_r \frac{d^2 \theta_o}{dt^2} + \frac{k_1 k_2}{r_a} \frac{d\theta_o}{dt} = -\frac{k_1 e}{r_a} \text{ for } \varepsilon < -\varepsilon_0 \dots [12]$$

Equation [10] describes the forward motion, Equation [11] the braking action, and Equation [12] the reverse motion.

These equations are in terms of per unit angle and seconds of time. Motors may have a wide range of rated speeds and armature inertia, and it will be convenient to express time in terms of a dimensionless unit such as a "time constant." Dimensionless time is expressed as

$$\tau = \frac{t}{T}$$

where

$$T = \frac{J \theta_r r_a}{M_r k_1 k_2} \text{ sec}$$

A new velocity and acceleration are then written as

$$\frac{d\theta_o}{dt} \frac{dt}{d\tau} = \frac{d\theta_o}{d\tau}$$

$$= \dot{\phi}_0$$

hence, with the relation $(dt)/(d\tau) = T$

$$\frac{d\theta_o}{dt} = \frac{1}{T} \dot{\phi}_0 \dots [13]$$

and in a similar manner

$$\frac{d^2 \theta_o}{dt^2} = \frac{1}{T^2} \ddot{\phi}_0 \dots [14]$$

Equations [10], [11], and [12] are then written as

$$\ddot{\phi}_0 + \dot{\phi}_0 = + \frac{J r_a \theta_r e}{M_r k_1 k_2} \varepsilon > \varepsilon_0 \dots [15]$$

$$\ddot{\phi}_0 + \dot{\phi}_0 = 0 \quad -\varepsilon_0 < \varepsilon < +\varepsilon_0 \dots [16]$$

$$\ddot{\phi}_0 + \dot{\phi}_0 = - \frac{J r_a \theta_r e}{M_r k_1 k_2} \varepsilon < -\varepsilon_0 \dots [17]$$

The range of factors on the right of Equations [15] and [17] for normally designed motors may be

$$0.06 < r_a < 0.2 \text{ (dimensionless)}$$

$$0.8 < e < 1.5 \text{ (dimensionless)}$$

$$0.8 < k_1 < 1.5 \text{ (dimensionless)}$$

$$0.7 < k_2 < 2.0 \text{ sec}$$

$$0.5 < \frac{J\Theta_r}{M_r} < 2.0 \text{ sec}^2$$

and the dimensionless term $(J\Theta_r a_e)/(M_r k_1 k_2^2)$ may range from a minimum of 0.05 to a maximum of 1.5. Under actual conditions the value may cover a smaller range about 1.

The equations of motion, Equations [15], [16], and [17], are in terms of per unit motor-shaft angle and per unit time. It will be more convenient in discussing the servo performance to have the results in terms of the per unit error angle and per unit time

$$\phi_0 = n(\theta_i - \varepsilon) \text{ per unit} \dots [18]$$

In the usual case θ_i is some function of time and should be represented as $\theta_{i(t)}$; however, only three cases are of general importance and will be considered in this discussion as follows

$$\text{Case 1 } \theta_i(t) = \theta_{i(0)} \text{ radians} = \text{const} \dots [19]$$

$$\text{Case 2 } \theta_i(t) = mt + \theta_{i(0)} \text{ radians} \dots [20]$$

$$\text{Case 3 } \theta_i(t) = A \cos(\beta t + \alpha) \text{ radians} \dots [21]$$

Rewriting Equations [19], [20], and [21] in terms of τ and per unit angle

$$\text{Case 1 } \theta_i(\tau) = \theta_{i(0)} \text{ per unit} \dots [22]$$

$$\text{Case 2 } \theta_i(\tau) = \frac{mT}{\Theta_r} \tau + \theta_{i(0)} \text{ per unit} \dots [23]$$

$$\text{Case 3 } \theta_i(\tau) = \frac{A}{\Theta_r} \cos(\beta T \tau + \alpha) \text{ per unit} \dots [24]$$

From Equations [13], [14], and [18]

$$\dot{\phi}_0 = \frac{d}{d\tau} (\phi_0) = n \left(\frac{d}{d\tau} \theta_{i(\tau)} - \frac{d}{d\tau} \varepsilon \right) \dots [25]$$

$$\ddot{\phi}_0 = \frac{d^2}{d\tau^2} (\phi_0) = n \left(\frac{d^2}{d\tau^2} \theta_{i(\tau)} - \frac{d^2}{d\tau^2} \varepsilon \right) \dots [26]$$

Substituting Equations [25] and [26] in [15], [16], and [17] where

$$B = \frac{J r_a \Theta_r a_e}{M_r k_1 k_2^2 n} \dots [27]$$

then

$$\ddot{\varepsilon} + \dot{\varepsilon} = -B + \frac{d^2}{d\tau^2} \theta_{i(\tau)} + \frac{d}{d\tau} \theta_{i(\tau)} \varepsilon > \varepsilon_0 \dots [28]$$

$$\ddot{\varepsilon} + \dot{\varepsilon} = \frac{d^2}{d\tau^2} \theta_{i(\tau)} + \frac{d}{d\tau} \theta_{i(\tau)} - \varepsilon < \varepsilon < +\varepsilon_0 \dots [29]$$

$$\ddot{\varepsilon} + \dot{\varepsilon} = +B + \frac{d^2}{d\tau^2} \theta_{i(\tau)} + \frac{d}{d\tau} \theta_{i(\tau)} \varepsilon < -\varepsilon_0 \dots [30]$$

Equation [28] corresponds to Equation [15], Equation [29] to Equation [16], and Equation [30] to Equation [17].

Equations [28], [29], and [30] are general for the problem under study, and there remains only the substitution of Equations [19], [20], and [21] to formulate the equations for Cases 1, 2, and 3.

Case 1. From Equation [22] $\theta_{i(\tau)}$ is a constant, hence

$$\frac{d}{d\tau} \theta_{i(\tau)} = \frac{d^2}{d\tau^2} \theta_{i(\tau)} = 0$$

and Equations [28], [29], and [30] reduce to

$$\ddot{\varepsilon} + \dot{\varepsilon} = -B \quad \varepsilon > \varepsilon_0 \dots [31]$$

$$\ddot{\varepsilon} + \dot{\varepsilon} = 0 \quad -\varepsilon_0 < \varepsilon < +\varepsilon_0 \dots [32]$$

$$\ddot{\varepsilon} + \dot{\varepsilon} = +B \quad \varepsilon < -\varepsilon_0 \dots [33]$$

This problem has been discussed by MacColl (2) for a single value of the parameter B . Additional data are given here for a range of values of B .

Equations [31], [32], and [33] may be integrated by separation of variable. Since phase-plane diagrams are desired, let

$$\begin{aligned} \ddot{\varepsilon} &= \frac{d}{d\tau} \dot{\varepsilon} = \frac{d\dot{\varepsilon}}{d\varepsilon} \frac{d\varepsilon}{d\tau} \\ &= \frac{d\dot{\varepsilon}}{d\varepsilon} \dot{\varepsilon} \end{aligned}$$

and the equations become

$$\frac{d\dot{\varepsilon}}{d\varepsilon} \dot{\varepsilon} + \dot{\varepsilon} = -B$$

$$\frac{d\dot{\varepsilon}}{d\varepsilon} \dot{\varepsilon} + \dot{\varepsilon} = 0$$

$$\frac{d\dot{\varepsilon}}{d\varepsilon} \dot{\varepsilon} + \dot{\varepsilon} = +B$$

upon integration there results

$$\varepsilon = -B - \dot{\varepsilon} + B \ln(B + \dot{\varepsilon}) + \text{const} \quad \varepsilon > \varepsilon_0 \dots [34]$$

$$\varepsilon = -\dot{\varepsilon} + \text{const} \quad -\varepsilon_0 < \varepsilon < +\varepsilon_0 \dots [35]$$

$$\varepsilon = +B - \dot{\varepsilon} - B \ln(-B + \dot{\varepsilon}) + \text{const} \quad \varepsilon < -\varepsilon_0 \dots [36]$$

These equations completely represent the relay servo operation in the phase plane. It should be noted that the ε -curves as a function of $\dot{\varepsilon}$ are determinable to a constant and hence, once a curve is determined, any other curve may be found by shifting the first curve parallel to the ε -axis.

Fig. 2 illustrates curves for various values of B from 0 to 4, and may be used directly for design.

Case 2. The derivatives of Equation [23] are

$$\frac{d}{d\tau} \theta_{i(\tau)} = \frac{mT}{\Theta_r}$$

which is a constant D

$$\frac{d^2}{d\tau^2} \theta_{i(\tau)} = 0$$

and Equations [28], [29], and [30] become

$$\ddot{\varepsilon} + \dot{\varepsilon} = -B + D \quad \varepsilon > \varepsilon_0 \dots [37]$$

$$\ddot{\varepsilon} + \dot{\varepsilon} = +D \quad -\varepsilon_0 < \varepsilon < +\varepsilon_0 \dots [38]$$

$$\ddot{\varepsilon} + \dot{\varepsilon} = +B + D \quad \varepsilon < -\varepsilon_0 \dots [39]$$

Upon integration in the same manner as for Case 1, the equations reduce to

$$\varepsilon = -(B - D) - \dot{\varepsilon} + (B - D) \ln[(B - D) + \dot{\varepsilon}] + \text{const} \quad \varepsilon > \varepsilon_0 \dots [40]$$

$$\varepsilon = D - \dot{\varepsilon} - D \ln(-D + \dot{\varepsilon}) + \text{const} \quad -\varepsilon_0 < \varepsilon < +\varepsilon_0 \dots [41]$$

$$\varepsilon = +(B + D) - \dot{\varepsilon} - (B + D) \ln[-(B + D) + \dot{\varepsilon}] + \text{const} \quad \varepsilon < -\varepsilon_0 \dots [42]$$

FIG. 2

These equations represent the relay operation in the phase plane. It should be noted that Equation [40] is similar to Equation [34] upon substitution of $B = (B - D)$ in Equation [40]; Equation [41] upon substitution of $B = D$ becomes Equation [36]; and Equation [42] upon substitution of $B = (B + D)$ becomes Equation [36]. Curves for design purposes may be obtained from Fig. 2.

Case 3. Case 3 is by far the most interesting in servo application because of the numerous occurrences, and the difficulty met in reducing the equations to phase-plane trajectories.

From Equation [24] the following derivatives are obtained

$$\frac{d}{d\tau} \theta_{i(\tau)} = -\frac{A}{\theta_r} \beta T \sin(\beta T \tau + \alpha)$$

$$\frac{d^2}{d\tau^2} \theta_{i(\tau)} = -\frac{A}{\theta_r} \beta^2 T^2 \cos(\beta T \tau + \alpha)$$

Substituting in Equations [28], [29], and [30] and defining

$$\frac{1}{\sqrt{1 + \beta^2 T^2}} = \cos \delta$$

and

$$\frac{\beta T}{\sqrt{1 + \beta^2 T^2}} = \sin \delta$$

then

$$\ddot{\epsilon} + \dot{\epsilon} = -B - \frac{A}{\theta_r} \beta T \sqrt{1 + \beta^2 T^2} \sin(\beta T \tau + \alpha + \delta) \quad \epsilon > \epsilon_0 \quad [43]$$

$$\ddot{\epsilon} + \dot{\epsilon} = -\frac{A}{\theta_r} \beta T \sqrt{1 + \beta^2 T^2} \sin(\beta T \tau + \alpha + \delta) \quad -\epsilon_0 < \epsilon < +\epsilon_0 \quad [44]$$

$$\ddot{\epsilon} + \dot{\epsilon} = +B - \frac{A}{\theta_r} \beta T \sqrt{1 + \beta^2 T^2} \sin(\beta T \tau + \alpha + \delta) \quad \epsilon < -\epsilon_0 \quad [45]$$

Case 3, as represented by Equations [43], [44], and [45], cannot be reduced to equations independent of time such as are necessary for phase-plane trajectories, and other methods must be used. Of course each equation is a linear differential equation with constant coefficients, and the solutions are well-known

factors of the time τ . One possible method of solving Case 3 is to compute step-by-step numerical data for each branch of the trajectory until it reaches steady state. Such a procedure is tedious, to say the least, and would not be practical for many solutions.

Since the purpose of this investigation is to determine design criteria, if possible, which would be sufficiently general to be of value to the servo user, a more efficient attack on the problem is needed. The mechanical differential analyzer is suited to this problem and was used to obtain over 50 solutions for wide ranges of the variables.

The phase-plane trajectories fell into three distinct classes as illustrated in Figs. 3, 4, and 5. Each class was characterized by a limit cycle having a period equal to that of the driving force, which in this case is the same as the period of the input angle, and having a stable motion that repeats over the same path for each successive cycle.

The limit cycle shown in Fig. 3 is somewhat analogous to resonance in linear systems in that the amplitude is large. From the point of view of the servo designer the motion appears to be unstable since the output does not follow the input with anything resembling a small error. By definition this type of motion will be called "unstable performance."

The limit cycle shown in Fig. 4 is more desirable from the operating point of view since the servo follows the input very closely in one direction, but lags the input in the other direction. By definition this type of motion shall be called "quasi-stable performance." In this motion the motor approaches one side of the dead space with approximately the velocity of the input angle and is able to follow the input for about a half-cycle. As indicated by the number of small loops, the motor-relay combination chatters about one edge of the dead space until the input angle reverses direction. At the instant of reversal the input velocity is zero, and the motor velocity is almost zero if not zero. The motor remains stationary until the input has moved sufficiently so that the error passes through zero to the other side of the dead zone. By this time the relative velocity of the input to the output is so great that the motor is unable to accelerate fast enough to overcome the input lead. The motor continues to follow without catching up until the input again reverses and the cycle repeats.

The limit cycle which is shown in Fig. 5 represents a desirable servo action in that the motor follows the input very closely by chattering about each side of the dead space. By defi-

FIG. 3

FIG. 4

FIG. 5

nition this type of motion shall be called "stable performance."

Since the relay servo is a physical system, and the parameters may be varied uniformly over wide ranges, one might expect that the three types of motion are different phases of the same motion, and that these phases have no sharp line of separation. Results obtained from the differential analyzer show that the phases do blend smoothly without sharply defined boundaries but it is possible to predict with a reasonable accuracy the type of motion.

Most of the phase-plane trajectories were taken for a dead space of $\pm\epsilon_0 = 0.1$ per unit angle and correlations for unstable, quasi-stable, and stable performance were referred to this dead space as a base. The best correlations were obtained by use of the following empirical expression

$$N = \frac{A\beta^2 T^2 \sqrt{1 + \beta^2 T^2 \epsilon_0}}{B, B^2 0.1} \quad \left. \begin{array}{l} N < 0.6 \text{ stable performance} \\ 0.6 < N < 0.85 \text{ quasi-stable performance} \\ N > 0.85 \text{ unstable performance} \end{array} \right\} \dots\dots\dots [46]$$

FIG. 6

Fig. 6 illustrates the type of correlation obtained. The fit is not perfect as there are two points not in the proper region but since sharp boundaries are not to be expected, the fit is sufficient for use as a design aid.

EFFECT OF DEAD-ZONE WIDTH

The empirical expression for N , Equation [46], indicates that as the dead-zone width increases, the servo becomes more unstable in performance. This is confirmed by the results shown in Figs. 7 to 11, inclusive, where the dead zone has been increased in width from zero to 0.15.

The phase-plane trajectories go from a perfectly stable performance, one that closes down on the point of zero error, Fig. 7, through successively less stable performances, Figs. 8 and 9,

FIG. 7

FIG. 8

FIG. 9

FIG. 10

FIG. 11

FIG. 12

FIG. 13

FIG. 14

FIG. 15

to the unstable performance in Fig. 12. The quasi-stable performance lies in the upper portion of the region defined by Equation [46], as indicated by a comparison of Figs. 9 and 10. The servo has not yet reached the quasi-stable state for the conditions of Fig. 9, and has just passed through that state for the conditions of Fig. 10.

The introduction of a relay time lag always decreases the stability of the servo. A comparison of Fig. 12 with Fig. 11 indicates that with time lag the maximum errors increase, and the limit cycle becomes more open.

A similar sequence, Figs. 13, 14, and 15, shows the effect of increasing dead-zone width on a trajectory for unstable performance. As predicted from Equation [46], the unstable limit cycle does not become more stable. On the other hand, once the servo is unstable and as long as the driving amplitude, A/θ_r , is less than one half the dead-zone width, ϵ_0 , the maximum error does not change appreciably. Table 1 in the Appendix shows that

for a change of dead zone from ± 0.1 to ± 0.75 , the maximum amplitude changes from 1.362 to 1.380. When the dead zone is ± 1.0 the maximum amplitude decreases slightly to 1.345, and when the dead zone exceeds the driving amplitude, the servo motor eventually comes to rest within the dead zone at such a point that the relays are never excited. The error trajectory is then equal to the input trajectory and is a circle or ellipse.

An estimate of the maximum error may be found from the expression derived in the Appendix.

The effect of relay time lag again increases the maximum error, for the case shown in Figs. 14 and 16, from a value of 1.377 to a value of 1.500.

ARMATURE-CIRCUIT RESISTANCE

It would appear from physical reasoning that upon increasing the armature-circuit resistance, the servomotor response would be more sluggish, and possibly the performance would be more stable. This is not the case, however, since the armature-cir-

FIG. 16 RELAY TIME DELAY = 0.1T

cuit resistance enters into both the parameter B and the time constant T . With a change in the time constant T , there is an accompanying change in the size of the units of T and a change in the size of the units of error velocity $\dot{\epsilon}$.

External resistance may be included in the armature circuit, provided it is included in the armature circuit for all conditions of operation. In other words, this analysis does not account for a voltage source with an internal resistance.

CONCLUSIONS

This study has indicated the difficulties encountered in relay servo investigations whenever the input is a function of time. There appears to be no direct method of solving for phase-plane trajectories in problems of the Case 3 type where the first and second derivatives of the input functions are functions of time. In these cases, one approach to the problem seems to be by way of differential-analyzer solutions for many varied cases, and an attempt to correlate the results.

The results of this study have been sufficiently encouraging to warrant a continuation of the work for various output-load systems and various types of motors. Additional studies should be made to account for such items as relay operating lag, static friction, and Coulomb friction.

Appendix

MAXIMUM ERROR OF A SERVO WITH UNSTABLE PERFORMANCE

Any servo, operating with a sinusoidally varying input, eventually must reach a limit cycle, on the phase plane, of a

period equal to the input period. If, for instance, the servo starts with a very large error, or error velocity, or a combination of both, the nature of the electrical connections are such as to reduce these errors to some minimum value. On the other hand, if the servomotor started from rest at the instant of both zero error and zero-error velocity, the change of input eventually would cause the relays to operate and start the motor. Once the motor has started, the amount of overshoot increases as it passes through the boundaries of the dead space until it reaches some limit such that the time for one cycle is just equal to the input period.

It is difficult to prove that these two limit cycles are identical, but mechanical solutions of the equations for the cases studied have always led to one and only one limit cycle for a given set of parameters. The limit cycle always has the same period as the servo input.

If the trajectory of the servo with unstable performance is considered, then since the input is symmetrical in its excursions about an average value, it might be expected that the servomotor and also the error would be symmetrical about some average value. For the phase-plane trajectory, the average value is the origin, and the trajectory has mirror symmetry about the origin with events occurring at the intersections of any line through the origin separated by a half-period in time.

It is proposed to solve the differential equations for each branch of the unstable trajectory, evaluate the constants of integration, the phase angle, and the time of travel over one branch, in order to have sufficient data to estimate the maximum error. The limit cycle to be investigated is shown in Fig. 17, with each branch lettered, and all points of importance numbered. The solutions are to be evaluated as if τ were zero at the beginning of each branch and the sinusoidal time functions adjusted to fit the junction points.

The period of the unstable servo is $(2\pi)/(\beta T)$ and the half-period is $\pi/(\beta T) = \Gamma$.

Reference to Fig. 17 and the condition of mirror symmetry

$$\left. \begin{aligned} \epsilon_1 &= -\epsilon_3 = \epsilon_0 \\ \dot{\epsilon}_1 &= -\dot{\epsilon}_3 \end{aligned} \right\} \dots\dots\dots [47]$$

also

$$\left. \begin{aligned} \epsilon_2 &= \epsilon_4 = \epsilon_0 \\ \dot{\epsilon}_2 &= \dot{\epsilon}_4 \end{aligned} \right\} \dots\dots\dots [48]$$

The equations for each branch of the trajectory as obtained from the differential equations [43], [44], and [45] are as follows

Branch U

$$\epsilon = P_1 + P_2 e^{-\tau} - B\tau + \frac{A}{\theta_r} \cos(\beta T\tau + \alpha) \dots\dots [49]$$

$$\dot{\epsilon} = -P_2 e^{-\tau} - B - \frac{A}{\theta_r} \beta T \sin(\beta T\tau + \alpha) \dots\dots [50]$$

Branch V

$$\epsilon = P_4 + P_5 e^{-\tau} + \frac{A}{\theta_r} \cos(\beta T\tau + \alpha) \dots\dots [51]$$

$$\dot{\epsilon} = -P_5 e^{-\tau} - \frac{A}{\theta_r} \beta T \sin(\beta T\tau + \alpha) \dots\dots [52]$$

Branch W

$$\epsilon = P_6 + P_7 e^{-\tau} + B\tau + \frac{A}{\theta_r} \cos(\beta T\tau + \alpha) \dots\dots [53]$$

$$\dot{\epsilon} = -P_7 e^{-\tau} + B - \frac{A}{\theta_r} \beta T \sin(\beta T\tau + \alpha) \dots\dots [54]$$

LIMIT CYCLE FOR A RELAY SERVO.

FIG. 17 LIMIT CYCLE FOR A RELAY SERVO

Branch X

$$\varepsilon = P_9 + P_{10}e^{-\tau} + \frac{A}{\Theta_r} \cos(\beta T\tau + \alpha) \dots [55]$$

$$\dot{\varepsilon} = -P_{10}e^{-\tau} - \frac{A}{\Theta_r} \beta T \sin(\beta T\tau + \alpha) \dots [56]$$

It can be shown by use of the symmetry condition, that

$$\begin{aligned} P_4 &= -P_1 \\ P_7 &= -P_2 \quad \tau_u = \tau_w \\ P_9 &= -P_4 \quad \tau_v = \tau_x \\ P_{10} &= -P_5 \end{aligned}$$

Also

$$\tau_u + \tau_v = \Gamma \dots [57]$$

and it is necessary to consider only Branches U and V in determining the constants, $P_1, P_2, P_4, P_5, \alpha, \tau_u$.At point 1 for $\tau = 0$ on Branch U

$$\varepsilon_1 = P_1 + P_2 + \frac{A}{\Theta_r} \cos \alpha = \varepsilon_0 \dots [58]$$

$$\dot{\varepsilon}_1 = -P_2 - B - \frac{A}{\Theta_r} \beta T \sin \alpha \dots [59]$$

At Point 3 for $\tau = \tau_u$ on Branch U

$$\varepsilon_3 = P_1 + P_2 e^{-\tau_u} - B\tau_u + \frac{A}{\Theta_r} \cos(\beta T\tau_u + \alpha) = \varepsilon_0 \dots [60]$$

$$\dot{\varepsilon}_3 = -P_2 e^{-\tau_u} - B - \frac{A}{\Theta_r} \beta T \sin(\beta T\tau_u + \alpha) \dots [61]$$

At Point 4 for $\tau = 0$ on Branch V

$$\varepsilon_4 = P_4 + P_5 + \frac{A}{\Theta_r} \cos(\beta T\tau_u + \alpha) = \varepsilon_0 \dots [62]$$

$$\dot{\varepsilon}_4 = -P_5 - \frac{A}{\Theta_r} \beta T \sin(\beta T\tau_u + \alpha) \dots [63]$$

Note that $(\beta T\tau_u + \alpha)$ is the angle that the input has at the start of Branch V.At Point 5 for $\tau = \tau_v$ on Branch V

$$\varepsilon_5 = P_4 + P_5 e^{-\tau_v} + \frac{A}{\Theta_r} \cos[\beta T(\tau_u + \tau_v) + \alpha]$$

Since $\tau_u + \tau_v = \Gamma$, and $\beta T\Gamma = \pi$

$$\varepsilon_5 = P_4 + P_5 e^{-(\Gamma - \tau_u)} - \frac{A}{\Theta_r} \cos \alpha = -\varepsilon_0 \dots [64]$$

$$\dot{\varepsilon}_5 = -P_5 e^{-(\Gamma - \tau_u)} + \frac{A}{\Theta_r} \beta T \sin \alpha \dots [65]$$

From the relations, Equations [47] and [48], and the Equations [58] through [65], the constants of integration are determined in functions of τ_u .

$$P_4 = -\frac{1}{2} B\tau_u \dots [66]$$

$$P_1 = B \left(1 + \frac{1}{2} \tau_u \right) \dots [67]$$

$$P_2 = -B \left(\frac{1 + e^{-(\Gamma - \tau_u)}}{1 + e^{-\Gamma}} \right) \dots [68]$$

$$P_5 = B \left(\frac{1 - e^{-\tau_u}}{1 + e^{-\Gamma}} \right) \dots [69]$$

Substitute Equations [47] and [48] in Equation [58] and solve for $\cos \alpha$

$$\cos \alpha = \frac{\Theta_r}{A} \left[\varepsilon_0 - B \left(1 + \frac{1}{2} \tau_u \right) + B \left(\frac{1 + e^{-(\Gamma - \tau_u)}}{1 + e^{-\Gamma}} \right) \right] \dots [70]$$

Substitute Equations [50] and [51] in Equation [62] and solve for $\cos(\beta T\tau_u + \alpha)$

$$\cos(\beta T\tau_u + \alpha) = \frac{\Theta_r}{A} \left[\varepsilon_0 + \frac{1}{2} B\tau_u - B \left(\frac{1 - e^{-\tau_u}}{1 + e^{-\Gamma}} \right) \right] \dots [71]$$

It is not possible to solve Equations [70] and [71] explicitly for α and τ_u , but values may be obtained by numerical or graphical methods.It should be observed that if ε_0 is zero, then $\tau_u = \Gamma$ and $\tau_v = 0$. For this case Equations [66] to [71] reduce to

$$P_1 = B \left(1 + \frac{1}{2} \Gamma \right) \dots [72]$$

$$P_2 = -B \left(\frac{2}{1 + e^{-\Gamma}} \right) \dots [73]$$

$$P_4 = -\frac{1}{2} \Gamma B \dots [74]$$

$$P_5 = B \left(\frac{1 - e^{-\Gamma}}{1 + e^{-\Gamma}} \right) \dots [75]$$

$$\cos \alpha = \frac{B\Theta_r}{A} \left[\left(\frac{2}{1 + e^{-\Gamma}} \right) - \left(1 + \frac{1}{2} \Gamma \right) \right] \dots [76]$$

Equation [71] reduces to Equation [76].

The point of maximum error occurs at the point $\dot{\varepsilon} = 0$ and hence an exact solution may be obtained numerically for $\tau(\dot{\varepsilon} = 0)$ upon substitution of values for Equation [48], α , and τ_u obtained from Equations [66], [70], and [71]. The value of $\tau(\dot{\varepsilon} = 0)$, together with Equation [48], α and τ_u may then be substituted in

Equation [49] for ϵ_{\max} . This procedure represents considerable numerical work that is necessary only for an exact result. In most practical cases the results will be sufficiently accurate if $\tau(\epsilon=0)$ is taken as $1/2\tau_w$. Again, if a greater tolerance is allowable in the values of ϵ_{\max} , the value obtained from the case of $\epsilon_0 = 0$ may be used, and the values from Equations [72], [73], [76], and $\tau = 1/2\Gamma$ substituted in Equation [49].

The maximum error for the case where $A/\theta_r = 1$, $B = 1$, $\beta T = 1$, and ϵ_0 varies from zero to 1 is shown in Table 1, repre-

TABLE 1 VARIATION IN ϵ_{\max} WITH VARIATION OF ϵ_0

ϵ_0	ϵ_{\max}	Deviation, per cent
0	1.359	0 (base)
0.1	1.362	+0.2
0.25	1.366	+0.5
0.50	1.377	+1.2
0.75	1.380	+1.5
1.00	1.345	-1.0

senting results from differential-analyzer curves, and is well within ± 2 per cent of the value obtained for $\epsilon_0 = 0$.

Cable-Pulley Friction¹

By W. E. SCHORR,² NEW YORK, N. Y.

The factors contributing to the friction in cable-pulley or rope systems are analyzed, and an empirical equation for calculating this friction is derived.

NOMENCLATURE

The following nomenclature is used in the paper:

- d = diameter of cable, in.
- d_g = diameter of pulley-throat groove, in.
- d_s = diameter of pulley shaft, in.
- D = effective diameter of pulley, in.
- e = misalignment of cable, deg
- f_b = coefficient of friction of bearing, based on shaft diameter
- f_b' = coefficient of friction of bearing, based on pulley diameter
- f_c = cable bending factor
- f_p = coefficient of sliding friction of cable-pulley materials
- F_B = bearing friction, lb
- F_c = cable bending friction, lb
- F_I = friction due to inertia effects, lb
- F_{max} = maximum cable bending friction, lb
- F_T = total friction, lb
- I = inertia effects
- l = length of lay of cable, in.
- n = number of strands in cable (not including core)
- N = normal load on pulley, lb
- T = cable tension, lb
- θ = angle of cable bend, deg
- θ_c = critical angle of cable bend, deg
- θ_f = angle of full cable bend, deg
- ψ = pulley design factor

The symbols are illustrated in Fig. 1.

INTRODUCTION

Cable-pulley systems or rope drives are used both for the transmission of power from one rotating shaft to another and for the transmission of a force or motion from one point to another. In the former case, much friction is desired between the pulley and the cable in order that the power of the driver pulley be transmitted undiminished to the driven pulley. Basic information is readily available on the variables involved in this application.

In the case of motion transmission, such as is experienced in control systems, hoisting, haulage and transporting services, however, the transfer of a force by means of a cable is desired. The pulleys are used merely to direct the force from the point of application to the point of action. The presence of large frictional losses in such systems has a detrimental effect upon the operation and life of the system and should be avoided.

This problem becomes especially important in control systems such as are used in aircraft where limitations of equipment and design exist, where quick and dependable action is of utmost importance, and where manual overcoming of the friction of the system may result in undue exhaustion of the pilot. In other applications, even though the problem is of lesser importance, the minimizing of the friction of the system will result in higher efficiency and more satisfactory operation.

Basic information as to the relative importance of the factors involved in these applications is lacking, however, and little data exist which will enable the energy losses of the systems to be calculated. This paper studies some of the variables involved and condenses them into a useful empirical equation as determined from experimental data.

PRELIMINARY ANALYSIS

The preliminary analysis indicates that the factors involved in cable-pulley total friction F_T are d , cable diameter; D , effective pulley diameter; θ , angle of cable bend; T , cable tension; e , cable misalignment; f_b , f_c , f_p , bearing, cable, and pulley friction factors, respectively; ψ , pulley design factor; and I , inertia factor. The coefficient of friction f_b will depend upon the type of bearing (plain, ball, or roller), and the operating conditions. The cable bending factor f_c will depend upon the design, flexibility, construction, and material of the cable. The coefficient of sliding friction f_p will depend upon the materials of the cable and the pulley. The pulley factor ψ will depend upon the material and design of the pulley, such as groove shape, groove radius, and so forth.

Moreover, the total friction arises from several sources and may be separated into (1) friction in the bearing F_B , (2) internal friction of the cable in flexing and digging into the pulley F_c , and (3) the energy expended in overcoming the inertia effects of the system, F_I

$$F_T = F_B + F_c + F_I \dots \dots \dots [1]$$

Bearing Friction, F_B . The loss due to the sliding contact of the rotating pulley on its shaft may be expressed as

$$F_B = f_b' N \dots \dots \dots [2]$$

where f_b' is the coefficient of friction at the point where F_B is applied.

The coefficient of friction f_b is usually expressed in terms of the

shaft diameter, d_s . However, since the bearing loss must be overcome by a force applied at the effective pulley diameter D , the coefficient must be expressed in terms of the pulley diameter (f_b'), or a correction ratio be applied

$$f_b' = f_b \frac{d_s}{D} \quad [3]$$

The normal load N may be expressed in terms of the cable tension T and the angle of cable bend θ as shown in Fig. 2. Thus

$$N = T (2 - 2 \cos \theta)^{1/2} \quad [4]$$

FIG. 2 RESOLUTION OF FORCES

Therefore the bearing friction may be given as

$$F_b = f_b' T (2 - 2 \cos \theta)^{1/2} \quad [5]$$

Cable Bending Friction, F_c . The wire rope used in control systems and wire drives is composed of several wires which are helically wound around another wire to form a strand. Several of these strands are then helically wound around a core (wire or fiber) to complete the cable. In bending around a pulley or sheave, the individual wires must be free to move in order to conform to the contour of the pulley. This movement expends energy, since it will result in tension in the outer wires of the bend and compression in the inner wires in contact with the pulley. Moreover, there will be sliding friction as the individual wires rub against one another and against the surface of the pulley as the cable conforms to the desired curvature. The cable bending friction F_c will be a function of d , D , θ , T , e , f_c , f_p , and ψ , as previously defined.

Friction Due to Inertia Effects, F_i . Since more initial force is required to start a system moving from rest, overcoming inertia effects, than is necessary to keep it moving, there exists both a static and a dynamic condition of friction in a cable-pulley system. The inertia effects will depend upon the weights of the moving components of the system, their moments of inertia, the velocity of the cable in moving over the pulleys, and any vibrations present in the system.

Test Conditions. The foregoing analysis indicates that the variables involved are too numerous for all to be considered in the present investigation. However, since the problem of friction is not as important where the pulleys are few and where factors such as weight and space are secondary, the actual tests will be conducted with regard to an application where the conditions are serious, for example, the control system of an aircraft. The test data obtained will therefore be directly applicable only to these systems (or to systems using identical test specimens), but the general form of the solutions will hold for all applications, except for actual values of constants and coefficients.

The components of aircraft control systems have been specified by military and governmental agencies, and thus several of the variables involved will remain constant in all such systems and need not be investigated.

Cable. Specifications require that 7×19 extra-flexible stainless-steel cable be used. The present tests were limited to the use of this type of cable, and so the cable factor f_c was not varied.

Pulley. AN 210 (AN-FFP-796) micarta pulleys with anti-

friction ball bearings (K series) were used. This limits f_p to micarta-steel, ψ to AN 210 design, and f_b to antifriction ball bearings.

Operating Conditions:

1 The combinations of cables and pulleys that may be used together are specified by AN-FFP-796, and so only these were tested.

2 Misalignment e must be avoided and kept below $1\frac{1}{2}$ deg in all acceptable systems. The effects of misalignment were kept at zero, and thus variations were not investigated in this test.

3 Since vibrations always exist in an aircraft while in flight, and since no excessive linear velocities of cable are involved, the static friction is eliminated and therefore only the dynamic friction was investigated (eliminates F_i).

The foregoing limitations reduce the variables to be investigated to d , D , θ , and T and changes the total friction to the total dynamic friction so that

$$F_T = F_b + F_c \quad [6]$$

TEST SETUP AND METHOD

Since the preliminary analysis indicated that the variables D , d , θ , and T must be investigated, a test jig was designed which would allow for the necessary variation in these factors. The test setup is shown in Fig. 3.

FIG. 3 SETUP USED IN CABLE-PULLEY FRICTION TESTS

FIG. 4 MOUNTING OF PULLEYS

The apparatus accommodated all standard pulleys from 1 to 6 in. diam, in combination with all cable sizes, and permitted all angles of cable bend from 0 to 180 deg at any desired cable tension. Four identical test pulleys were tested on the jig at one time, all at the same cable bend as determined by the angle disk. A close-up showing the mounting of the test pulleys is given in Fig. 4. The cable tension was adjusted by means of a turnbuckle and measured by a dynamometer. A weighted tray and small spring scale were connected by means of a cord over an idler pulley to one groove of a double-grooved guide pulley, while the test cable ran over the second groove and over the four test pulleys. A force was applied on the scale (or the scale in

FIG. 9 TOTAL DYNAMIC FRICTION VERSUS CABLE DIAMETER
(4A pulley, 400-lb cable tension.)

conjunction with the weights in the tray), until the system moved at a constant velocity. The velocity or speed of the cable of the test was approximately 1.5 fps for a test distance of about 6 ft. The force as read on the scale plus the weights in the tray represented the friction of the entire system.

One run was taken at zero angle of cable bend. This represented the tare of the system, that is, the friction of the system minus the four test pulleys. By subtracting the tare value from the total value measured, the net friction of the test pulleys alone was determined. Since four test pulleys were involved, this net friction was divided by 4 to obtain the friction per pulley.

The pulley-cable combinations tested were as follows:

Pulley	Cable
3A	3/32, 1/8, 5/32, 3/16
4A	3/32, 1/8, 5/32, 3/16
5A	1/8, 5/32, 3/16, 1/4
6A	3/16, 1/4

The bearing-friction tests were conducted in two ways. For the light bearing loads, a very flexible fiber rope was wrapped around two identical test pulleys, and the force required to keep the system in motion at constant speed was measured. Since the fiber cord was very flexible, the cable bending friction was negligible, and the force applied merely overcame the friction present at the bearings of the two pulleys. The setup is illustrated in Fig. 5(a).

For the heavier bearings loads, a force was imposed on two stationary test pulleys by means of a cable-and-turnbuckle arrangement. The torque required to turn the shaft passing through the pulleys was then measured. The friction values resulting were divided by 2 to obtain the bearing friction per pulley. This setup is shown in Fig. 5(b).

TEST RESULTS

From the test data obtained, the following relationships were plotted for all of the pulley-cable combinations which were tested:

- Curve 1 Total friction versus cable tension (F_T vs T)
- Curve 2 Total friction versus cable bend (F_T vs θ)
- Curve 3 Total friction versus pulley diameter (F_T vs D)
- Curve 4 Total friction versus cable diameter (F_T vs d)
- Curve 5 Bearing friction versus normal load (F_B vs N)

Typical examples of Curves 1 to 4 are shown in Figs. 6 to 9, inclusive. Since the normal load N , may be expressed in terms of T and θ (see Equation [4]), the bearing-friction curves (F_B versus N) were redrawn in terms of the cable bend θ , for constant values of cable tension T .

Also, since it was determined originally that $F_T = F_B + F_c$ (see Equation [6]), the bearing friction was subtracted from the total friction, and the relationships for the cable-bending friction F_c were obtained.

The data and curves indicated immediately that F_T (F_B and F_c also) varied directly with the cable tension T within the test range, and so only the variables θ , D , and d required further consideration. Therefore the following curves were plotted:

- Curve 6 Bearing friction versus cable bend (F_B vs θ)
- Curve 7 Cable bending friction versus cable bend (F_c vs θ)
- Curve 8 Cable bending friction versus pulley diameter (F_c vs D)
- Curve 9 Cable bending friction versus cable diameter (F_c vs d)

Curves 6 to 9 are shown in Figs. 10 to 12, inclusive.

Bearing Friction, F_B . The test data indicated that the bearing friction was directly proportional to the normal load, and thus the initial analysis was substantiated. The equation for the bearing friction is therefore

$$F_B = f_b' T (2 - 2 \cos \theta)^{1/2} \dots \dots \dots [5]$$

Cable Bending Friction, F_c . The curve of cable bending friction versus cable bend (F_c versus θ) indicated that the friction increased parabolically from a zero cable bend, reached a maximum value, and then remained essentially constant at the maximum value up to a complete bend of 180 deg. This suggested that a critical angle of bend existed for every pulley-cable com-

FIG. 10 Friction Versus Cable Bend
(4A pulley, 1/16-in. cable, 400-lb cable tension.)

bination, an angle above which the cable bending friction was essentially independent of increased cable wrap. This critical angle θ_c was investigated, and an empirical equation in terms of d and D was derived. This was readily done since the curves of θ_c versus d , and θ_c versus D plotted approximately as straight lines on log-log paper, within the test range, Figs. 13 and 14. The derived equation was

$$\theta_c = 161 \frac{d^{0.5}}{D^{0.5}} \quad [7]$$

The value of the cable bending friction at the critical angle F_{\max} was found to be the maximum value of friction due to this source. Curves of F_{\max} versus d , and F_{\max} versus D , also plotted

FIG. 13 F_{\max} AND θ_c VERSUS
PULLEY DIAMETER
(400-lb tension.)

FIG. 14 F_{\max} AND θ_c VERSUS
CABLE DIAMETER
(400-lb tension.)

as straight lines on log-log paper, Figs. 13 and 14, and the following relationship was obtained

$$F_{\max} = T \frac{d^{1.92}}{D^{1.45}} \quad [8]$$

Below the critical angle, the cable bending friction is dependent upon all the variables θ , d , and D and increases parabolically with increasing cable bend. Using the values of θ_c and F_{\max} obtained, and assuming a parabolic variation, an empirical equation for the cable bending friction at subcritical angles was derived

$$F_c = T \frac{d^{0.92}}{D^{1.45}} \left[d - (\theta_c - \theta)^2 \frac{D}{(161)^2} \right] \quad [9]$$

Total Dynamic Friction, F_T . Since the total dynamic friction is the sum of the cable bending friction and the bearing friction, the derived equation for the total dynamic friction for $\theta < \theta_c$ is

FIG. 11 CABLE BENDING FRICTION VERSUS
PULLEY DIAMETER
(Critical cable angle, 400-lb cable tension.)

FIG. 12 CABLE BENDING FRICTION VERSUS
CABLE DIAMETER
(Critical cable angle, 400-lb cable tension.)

$$F_T = F_c + F_B$$

$$F_T = T \left\{ \frac{d^{0.92}}{D^{1.45}} \left[d - (\theta_c - \theta)^2 \frac{D}{(161)^2} \right] + f_b' (2 - 2 \cos \theta)^{1/2} \right\} \quad [10]$$

$$F_T = T \left\{ \frac{d^{0.92}}{D^{1.45}} \left[d - \left(161 \frac{d^{0.5}}{D^{0.5}} - \theta \right)^2 \frac{D}{(161)^2} \right] + f_b' (2 - 2 \cos \theta)^{1/2} \right\} \quad [11]$$

Since, in most applications, the angle of cable bend is greater than the critical value, the equation for total dynamic friction may be reduced to

$$F_T = T \left\{ \frac{d^{1.92}}{D^{1.45}} + f_b' (2 - 2 \cos \theta)^{1/2} \right\} \quad [12]$$

Examples of bearing friction, cable bending friction, and total dynamic-friction curves are shown in Fig. 10.

DISCUSSION OF TEST RESULTS

Cable Bending Friction. The existence of a critical angle of bend θ_c and a maximum value of cable bending friction F_{\max} may be explained as follows:

Internal friction in the cable is caused by the bending and unbending of the cable as it contacts and leaves the pulley. In conforming to the contour of the pulley, the individual wires and strands composing the cable must bend and rub against one another and against the pulley surface, thereby producing sliding friction. The actual bending occurs only at the points of tangency of the cable and the pulley, however, and once the cable has been bent through an angle great enough for the individual wires to reach equilibrium at the desired curvature, no further relative movement occurs until the point of unbending is reached. When an angle of cable bend greater than the critical angle is encountered, the cable sections which are bending and unbending at the points of tangency are developing friction, whereas the central section is merely fixed to the contour of the pulley and contributes nothing to the losses. A condition of maximum cable bending friction occurs, therefore, and this will exist when the critical or full bending angle has been reached.

The magnitude of the critical angle depends upon the diameters of the cable and the pulley, since these factors influence the severity of the bending required of the individual wires. Referring to available data,³ an angle of full bending is derived which depends upon the "lay" of the rope or cable. The length of lay of the cable l is defined as that distance measured parallel to the axis or center line of a cable in which a strand makes one com-

³ "Roebing Handbook," John A. Roebing's Sons Company, Trenton, N. J., 1947.

plete spiral or turn around the cable. According to the foregoing reference, once full bending is encountered, it makes no difference how great the departure (arc of contact with the pulley), the effect on the rope will be the same. The angle of full bending θ_f is given as

$$\theta_f = \frac{360}{\pi} \frac{l}{D} \quad [13]$$

This is the equation for the center angle of a circular segment whose diameter is D and whose length of arc is equal to l . For the 7×19 cable tested, the length of lay was determined to be approximately $l = 7.2 d$. Substituting this in Equation [13], we obtain

$$\theta_f = 825 \frac{d}{D} \quad [14]$$

The results of the present tests indicate, however, that within the test range, the critical angle θ_c , at least in so far as cable bending friction is concerned, is

$$\theta_c = 161 \frac{d^{0.5}}{D^{0.5}} \quad [7]$$

The constant 161 and the exponents are dependent upon f_c , f_p , n , and ψ .

Although the two equations differ, the idea of a "critical" angle is substantiated. One reason for the discrepancy may be that Equation [13] assumes that one full rope lay is necessary between the points of contact of pulley and cable before equilibrium of the individual wires occurs, whereas actual contact takes place against the sides of the pulley flanges and the actual distance between contact points may be less than one full rope lay. This would result in the critical angle θ_c being less than the calculated angle of full bending θ_f . Another factor involved is that of slippage between the cable and pulley surfaces at the points of contact. If slippage is present θ_c may be greater than θ_f , since relative movement between the wires would occur for a distance greater than one full rope lay.

Values of the critical angle θ_c (measured and calculated) and the angle of full bending θ_f are given in Table 1.

The maximum value of cable bending friction F_{\max} also depends upon d and D , inasmuch as more energy is expended in bending a given-size cable over a smaller-diameter pulley, or bending a larger-size cable over a given-size pulley. In the derived equation

$$F_{\max} = T \frac{d^{1.92}}{D^{1.48}}$$

the exponents of d and D are dependent upon the actual cables and pulleys tested. If galvanized or zinc-coated cable or less flexible cable, were used (thereby changing f_c and n), the exponent of d would increase. The use of steel or other material for the pulleys (changing f_p) would change the exponent of D . A change in pulley groove diameter or throat design (changing ψ) would result in changes of the exponents of both d and D . Regardless of the changes in materials and design, however, the general form of the equation would be similar, the actual values of the exponents being determined only by tests.

In some of the pulley-cable combinations tested, the test data indicated that the cable bending friction decreased somewhat after reaching the maximum value at the critical angle of cable bend. The results were inconclusive, however, and therefore this friction is assumed to remain constant at F_{\max} in the present analysis.

TABLE 1 COMPARISON OF CRITICAL ANGLE AND ANGLE OF FULL BENDING

Pulley diam, D , in.	Cable diam, d , in.	θ_c (measured), deg	θ_c (calculated), deg	θ_f , deg
1.656 (3A)	3/32	40	39.5	47
1.656 (3A)	1/8	42	44	62
1.656 (3A)	5/32	50	49.5	78
1.656 (3A)	3/16	62	57	101
3.156 (4A)	3/32	25	28	24.5
3.156 (4A)	1/8	30	32	33
3.156 (4A)	5/32	32	36	41
3.156 (4A)	3/16	40	39	49
4.592 (5A)	1/8	28	26.5	23
4.592 (5A)	5/32	30	29.5	28
4.592 (5A)	3/16	32	32.5	34
4.592 (5A)	1/4	38	38.5	45
5.592 (6A)	3/16	30	29.5	38
5.592 (6A)	1/4	32	33	37

Bearing Friction. According to earlier data,⁴ the loss of energy due to friction in the bearings arises from (1) the sliding contact between the balls and the separating pockets, (2) the rolling or internal friction of the steel due to deformation of the balls and races under load, (3) the slip which may occur in contact areas, and (4) the friction due to windage at the higher speeds. Since the tests were run at low speeds, friction due to windage was negligible.

The coefficients of friction for ball bearings as given in most literature range from 0.0005 to 0.0095, based on shaft diameters, depending upon the operating conditions.⁵ The actual values obtained in the present investigation, however, ranged from 0.013 to 0.032, based on shaft diameters (or 0.001 to 0.005, based on pulley diameters). The discrepancy is probably due to the fact that the literature values are for ideal, well-lubricated, new or clean conditions, whereas the test values represent actual service conditions. Qualitative tests conducted on pulleys with dusty or poorly lubricated bearings resulted in the coefficients of friction increasing to 0.032–0.075, and higher. The bearing coefficients as determined for the pulleys tested are given in Table 2.

The bearing friction was found to vary directly with the normal load, except for a slight initial sliding-contact friction which exists even at no-load conditions. In the analysis of the equation for bearing friction, this small initial friction was neglected,

TABLE 2 COEFFICIENTS OF BEARING FRICTION

Pulley no.	Pulley diam, D , in.	Shaft diam, d_s , in.	f_b	f_b'
3A	1.656	0.25	0.029	0.0044
4A	3.156	0.25	0.031	0.0024
5A	4.592	0.375	0.0147	0.0012
6A	5.592	0.375	0.0148	0.0010

and the coefficient of friction was assumed to be independent of load.

Since the bearing friction is directly proportional to the normal load, which in turn increases with the angle of cable bend (at constant cable tension), the bearing friction will increase continually with increase in cable bend.

Total Dynamic Friction. Very little data exist on the friction present in pulley-cable systems, and therefore comparative values are meager. The only data known to the author are the results given by Schorr,⁶ and Remington and Matthews.⁷ Comparison with these results are very good and are shown in Fig. 15,

⁴ "New Departure Handbook," New Departure Company, New London, Conn., vol. 11, 1939.

together with total friction values as calculated from the derived equation.

CONCLUSIONS

The conclusions derived from this investigation are as follows:

- 1 The friction in cable-pulley systems increases as follows:
 - (a) With increase in cable tension (linearly).
 - (b) With increase in angle of cable bend.
 - (c) With increase in cable diameter.
 - (d) With decrease in pulley diameter.
- 2 An empirical equation for determining the total dynamic friction in cable-pulley systems is

$$F_T = T \left\{ \frac{d^{0.92}}{D^{1.48}} \left[d - (\theta_c - \theta)^2 \frac{D}{(161)^2} \right] + f_b' (2 - 2 \cos \theta)^{1/2} \right\} \quad \theta < \theta_c$$

For most applications, this may be reduced to

$$F_T = T \left\{ \frac{d^{1.92}}{D^{1.48}} + f_b' (2 - 2 \cos \theta)^{1/2} \right\} \quad \theta \geq \theta_c$$

- 3 A critical angle of cable-bending friction exists, above which the friction becomes independent of increased cable wrap. The value of this critical angle depends upon the cable-pulley combination involved and is related as follows

$$\theta_c = 161 \frac{d^{1.5}}{D^{0.5}}$$

- 4 A maximum value of cable-bending friction exists at angles of cable bend equal to or greater than the critical angle. This maximum value may be expressed as

- 5 The coefficients of friction for ball bearings under actual

FIG. 15 COMPARATIVE TEST CURVES
(4A pulley, 1/16-in. cable, 400-lb tension.)

$$F_{max} = T \frac{d^{1.92}}{D^{1.48}}$$

service conditions are higher than those usually listed. The friction due to the bearings may therefore become a substantial part of the total friction in cable-pulley systems.

ACKNOWLEDGMENTS

The author gratefully acknowledges the helpful assistance of Prof. A. H. Church, not only as adviser, but also in obtaining the necessary equipment, space, and shop facilities for conducting the required tests. Many thanks are also due to members of the New York University Mechanical Engineering Laboratory personnel for their help in the construction of the test setup, to

Republic Aviation Corporation, and *Aero Digest* for the use of their material, and to John A. Roebling's Sons Company for supplying samples of cables and company publications.

Discussion

H. C. GUHL.⁸ The mathematical approach which has been made to evaluate design factors in cable systems is accurate and complete. Thereby the aircraft designer can select components of cable and pulleys which will permit operating loads within required design limits.

In the course of manufacture of aircraft control pulleys from phenolic laminated or macerated materials, many endurance tests have been made. With a precision bearing of low coefficient of friction, limits of endurance were established by heating and fraying of the cable. Cable friction in such cases is of predominant importance. Other cases developed where bearings were of low coefficient of friction but not precision-built, which would cause cable misalignment and thus produce high bearing and high cable friction to lower endurance limits. Certain plain bearings or those having high coefficient of friction would establish lowered endurance limits by failure from within the bearing. Again, cable failures may result from high coefficient of sliding friction of cable-pulley materials. Pulleys of semicushioning quality material, as cloth-reinforced phenolic products, provided increased endurance limits.

F. A. MATTHEWS.⁹ In his introduction the author gives as reasons for the importance of considering friction in the design of control systems, pilot fatigue and dependable action. Of equal or greater importance is the adverse effect of friction in the main flight controls on the aerodynamic stability of the airplane. Particularly in the case of control surfaces with a high percentage of aerodynamic balance does excessive friction play an extremely important part. Since, at the neutral position of the control surface in flight, forces on both sides of the surface are in balance, even small amounts of friction in the control system will upset this balance and allow sufficient surface deflection to change the attitude of the airplane without generating sufficient air load to return the surface to neutral. For example, a pilot in leveling off his ship after a maneuver has a tendency to overcorrect, due to the time lag between the movement of the surface and the response of the ship. In a good control system the surfaces, due to the lack of friction, are able to neutralize themselves, and the airplane maintains the level flight attitude. In a poor control system there is sufficient friction to prevent the surfaces from neutralizing themselves, and they must be neutralized manually. This condition results in hunting around the neutral position and instability or oscillation in the flight path.

In tests by the writer's company the apparatus used was very similar to that used by the author, with one exception: The four pulleys in the system on which the friction was being measured were mounted on a carriage which traveled on ball-bearing rollers on a machined track. Thus the cable remained stationary, and the pulleys moved along the cable. Motion was imparted to the carriage by means of a constant-speed motor which was attached to a cable connected to the carriage through a flexible bar to which a strain gage was attached. The load required to move the carriage was recorded by an SR-4 electric strain recorder. Test runs indicated that there was no appreciable variation in the load required to move the carriage through its entire travel. Inasmuch as the major concern of the tests

⁸ Manager, Micarta Division, Westinghouse Electric Corporation, Trafford, Pa.

⁹ Design Engineer, Lockheed Aircraft Corporation, Burbank, Calif.

was static friction, the carriage was moved very slowly—approximately $1/16$ ips.

In operation the carriage was placed in such a position as to allow a slight amount of slack in the operating cable, and the motor was then started. Thus, the initial stroke of the strain-recorder needle recorded the load required to overcome static friction and impart motion to the carriage, and subsequent recording was the dynamic friction at the speed previously mentioned. It was felt that this setup would result in freedom from small errors created by the necessity of determining visually the precise moment there was sufficient load to impart motion.

In conducting the tests it was found that there was some variation in friction measured in different spots in the same cable, and slightly more variation in different test specimens of the same type of cable cut from different reels made by the same manufacturer. These discrepancies were considered to be small enough to have negligible effect, since all curves resulting from the tests were the average of several test runs.

In the test conducted by the author, the effect of cable misalignment on cable-pulley friction was correctly assumed to be negligible in a properly designed control system. The writer's tests substantiate this assumption inasmuch as it was found that misalignment up to 2 deg had no appreciable effect on friction. It is interesting to note, however, that at the critical angle of cable wrap, the cable-pulley friction increased approximately 70 per cent as a straight-line function between 2 deg and 5 deg misalignment. The test conditions in this case were $3/16$ in cable on AN-210-4A pulley with a 500-lb rig load. Indications were, however, that the effects of misalignment above 2 deg were a variable function and seemed to decrease as angle of wrap of the cable on the pulley increased, within limits.

There is some disagreement with the assumption made by the author that vibration in the control system eliminates static friction and, therefore, only dynamic friction need be considered, as the assumption was not borne out in our test results. The assumption made by the writer's company was that the detrimental effects of friction in an airplane control system were due to the necessity of motion being imparted, either by the pilot or by the control surface, to a system temporarily substantially at rest.

Undoubtedly static friction is affected by vibration, and dynamic friction must also be considered in an analysis made of a control system during its design stages. However, one of the premises on which the tests at the writer's company were based is that friction in a control system being detrimental, it would be the better plan to follow a conservative course in the analysis of friction during the control-system design and use static friction in the analysis. This would allow those benefits resulting from vibration to offset the unknowns encountered in the complete system, such as congealed grease in pulley and hinge bearings, warped control-surface hinge lines, unbalanced masses in control-system elements such as quadrants, control columns, and tolerances in the balance of the control surfaces themselves.

Inasmuch as friction is most detrimental at or near the stable flight attitude of the airplane, corrections are of necessity small and usually at very low rates of speed. Therefore, it was felt that the dynamic friction would approach closely the values of static friction, and, again, using static friction would be the better course to follow.

Although there is an almost infinite number of variables to be considered in attempting to determine the effect of vibration on friction, it was decided that tests of a simple nature could be conducted and trends established, although no definite conclusions could be reached. In this test setup the entire apparatus was vibrated at varying frequencies and amplitudes. The trends established were as follows:

1 There is an over-all reduction in static friction which varies to some extent with both frequency and amplitude.

2 The reduction in friction varies in inverse ratio to the angle of wrap of the cable around the pulley.

3 The reduction in friction varies as a direct ratio of the rig load in the cable.

4 Within the scope of the tests conducted, the variation in friction appeared to be independent of the critical angle of wrap or cable bend.

5 Within the scope of the tests, the variation of friction with vibration appeared to be independent of the speed of cable travel.

It was concluded as a result of the tests that, although vibration served to reduce static friction somewhat, it did not eliminate it as a factor. In all tests conducted, both with and without vibration, it was found that the "breakaway" friction or force required to start motion between pulleys and cable was higher than the force required to maintain motion. This apparent failure to eliminate static friction may be ascribed to the fact that in most circumstances the motion of a cable in a control system under vibration is found to be perpendicular to the axis of the cable rather than along the axis. It is even conceivable to suppose that conditions of amplitude and frequency could exist which would increase the static friction of the system.

Tests of a simple nature within the scope of the test apparatus were also conducted to compare dynamic friction at slow speeds with static friction. It appeared that at the speeds possible without revising the test apparatus, there was a slight reduction of static friction once motion was started, but that up to a point there was actually a slight increase in force required to maintain motion as the speed was increased. No attempt was made to determine the cause of this increase, as a further increase in speed served to reduce the force required. Table 3, herewith, gives data typical of the results obtained.

TABLE 3 CABLE-PULLEY FRICTION IN POUNDS, AS AFFECTED BY SPEED AND ANGLE OF WRAP

($3/16$ -in-diam 7×19 zinc-coated cable on AN-210-4A pulleys at 500-lb rig load)

Angle of wrap, deg	Speed of cable travel				
	Static	0.06 ips	0.125 ips	0.25 ips	0.50 ips
10	1.6	1.5	1.8	1.8	1.75
20	3.6	3.3	3.54	3.5	3.4
30	4.3	4.2	4.74	4.6	4.25
45	5.0	4.95	5.1	4.75	4.75
90	5.4	5.0	5.31	5.4	5.5
180	5.4	5.45	6.18	6.20	6.5

It is quite apparent from these results that no definite comparison or conclusions could be reached without further testing. It was felt, however, that the decision to use static friction in control-system analysis would not be erroneous inasmuch as the speeds covered by the tests were well within the range of cable speeds encountered in the airplane in making small corrections necessary to maintain level flight.

As mentioned previously, the discrepancies between results obtained from independent tests by the writer's company and those obtained by the author in both test and mathematical analysis are small, and the over-all results corroborate one another within the accuracy necessary to conduct a satisfactory analysis of a control system where there are other elements introducing small amounts of friction in the complete system.

An indirect substantiation of the author's analytical method of determining friction may be gained in comparing the results as obtained by the analytical method and the Vega tests in Fig. 15 of the paper, and the comparison between the calculated and actual measured results obtained in using the Vega curves in calculating the friction in the flight controls on the P2V Neptune bomber which are as follows:

Aileron system, couple at rim of wheel...Calc. 3.07 lb, actual 3.1 lb
 Elevator system, force at top of column...Calc. 4.58 lb, actual 4.5 lb
 Rudder system, force at pedal pivot...Calc. 12.7 lb, actual 12.5 lb

It appears that the author's source of information on specifications covering the requirements of aircraft control systems is somewhat inaccurate; 7 X 19 extra-flexible stainless-steel cable is not required in aircraft controls, except under certain specific conditions such as resistance to corrosive fumes, liquids, etc. Government specifications allow the use of the following types of 7 X 19 extra-flexible cable:

- 1 Stainless steel uncoated to Specification MIL-C-5424
- 2 Carbon steel tin-coated to Specification MIL-C-1511
- 3 Carbon steel zinc-coated to Specification MIL-C-1511

In the writer's company tests, the difference in cable bending friction found in testing stainless-steel cable and tinned carbon-steel cable was almost imperceptible, and the same values are used for both types of cable. Tinned carbon-steel cable is used predominantly in the aircraft industry at present—the deflection characteristics of stainless-steel cable being such that it is extremely difficult to meet deflection characteristics as required by specification with the use of this material. Zinc-coated carbon-steel cable was introduced during the last war to conserve tin, a critical material, and although not generally in use at present its use is still permissible, and it probably would be required in the event of another war.

The writer's tests indicate that the cable bending friction of zinc-coated carbon-steel cable is approximately 30 per cent higher than the cable bending friction of tinned carbon-steel cable. If the maximum benefits of the analytical method introduced by the author are to be achieved, exponents should be developed for (d) in the formulas.

In conclusion it is suggested that the use of the analytical method for calculating the friction in control systems might become unwieldy and laborious, in that over a period of time the same equation would be solved repeatedly; particularly in the case of those conditions where the critical angle of wrap is not reached would this be true. By comparison it would be much simpler to develop curves or nomographs by the analytical method, which could be used repeatedly without the necessity of solving the equations.

AUTHOR'S CLOSURE

Mr. Guhl supplies interesting information regarding the endurance factors involved in cable-pulley friction. Although the simplified equations for cable-pulley friction (Equation [10] and [12]

given in this paper do not indicate the direct effects of the coefficient of sliding friction of cable-pulley materials, f_p , and the cable bending factor, f_c , a more complicated equation being developed by the author does attempt to include these factors directly in the equation.

Mr. Matthews' remarks concerning cable-pulley friction and the aerodynamic stability of the airplane are absolutely correct. Reference to the aerodynamic phase of the control system was purposely omitted since the friction present in cable-pulley systems is a general engineering problem, and the author did not wish to burden the design engineer with the aerodynamic aspects of a specific application.

The investigation conducted by the author included quantitative measurements of both static and dynamic friction, and also the qualitative effects of vibration on these frictions. The results obtained for static friction, however, were not as satisfactory as those obtained for the dynamic friction as regards the analytical treatment which was the purpose of this paper. The difference between static and dynamic friction was found to be relatively low, and to vary with pulley size, cable tension, and angle of cable bend. As noted by Mr. Matthews, the values of dynamic friction and static friction would approach each other at or near the stable flight attitude of the airplane, where friction would be most detrimental, and in the present case the more satisfactory data of the dynamic friction made it more adaptable to a mathematical analysis.

The author is in complete agreement with Mr. Matthews with regard to the many variables to be considered if vibration is to be included in this problem. Since the analytical investigation had to be kept within reasonable bounds, the quantitative effects of vibration were omitted and the qualitative tests conducted were used merely to indicate that the presence of vibration tended to reduce the static friction and to make it approach the value of the dynamic friction. The trends established by Mr. Matthews, however, are most interesting and informative.

The cables used in the tests were limited to those covered by Specification AN-RR-C-48, since this was the Government specification for the aircraft concerned (Republic XP-69) at that time, 1942. As pointed out in the paper, for coverage of all possible applications (aircraft or otherwise) the exponents of d and D and the constant of Equation [7] must be obtained for every type of cable and pulley in use.

The analytical investigation was conducted not only to supply design information for one of the more common combinations of cable pulley used, but also to indicate the basic effects of some of the variables involved in the general problem.
